**Environmental Significance Statement** for “Raw Material Recovery from Hydraulic Fracturing Residual Solid Waste with Implications for Sustainability and Radioactive Waste Disposal” by Moses A. Ajemigbitse, Fred S. Cannon, Mark Klima, James C. Furness, Chris Wunz, and Nathaniel R. Warner.

Energy production by hydraulic fracturing consumes significant volumes of raw materials (sand, clay and water). Conventionally, the solid wastes from this process are disposed to landfills despite containing recoverable raw materials. In addition, natural radioactivity from the formation returns to the surface with the flow of oil or gas and co-produced water. This radioactivity can often become concentrated in the solid waste. In a bid to make hydraulic fracturing more sustainable, we explored a treatment process of this solid waste that could reclaim raw materials; reduce waste volumes; and a reduce/mitigate radioactivity in the environment.

### 5 **Abstract**

6 Unconventional oil and gas residual solid wastes are generally disposed in municipal waste  
7 landfills (RCRA Subtitle D), but they contain valuable raw materials such as proppant sands. A  
8 novel process for recovering raw materials from hydraulic fracturing residual waste is presented.  
9 Specifically, a novel hydroacoustic cavitation system, combined with physical separation  
10 devices, can create a distinct stream of highly concentrated sand, and another distinct stream of  
11 clay from the residual solid waste by the dispersive energy of cavitation conjoined with  
12 ultrasonics, ozone and hydrogen peroxide. This combination cleaned the sand grains, by  
13 removing previously aggregated clays and residues from the sand surfaces. When these unit  
14 operations were followed by a hydrocyclone and spiral, the solids could be separated by particle  
15 size, yielding primarily cleaned sand in one flow stream; clays and fine particles in another; and  
16 silts in yet a third stream. Consequently, the separation of particle sizes also affected radium  
17 distribution – the sand grains had low radium activities, as lows as 0.207 Bq/g (5.6 pCi/g). In  
18 contrast, the clays had elevated radium activities, as high as 1.85 – 3.7 Bq/g (50 – 100 pCi/g) –  
19 and much of this radium was affiliated with organics and salts that could be separated from the  
20 clays. We propose that the reclaimed sand could be reused as hydraulic fracturing proppant. The

1  
2  
3 21 separation of sand from silt and clay could reduce the volume and radium masses of wastes that  
4  
5 22 are disposed in landfills. This could represent a significant savings to facilities handling oil and  
6  
7  
8 23 gas waste, as much as \$100,000 – \$300,000 per year. Disposing the radium-enriched salts and  
9  
10 24 organics downhole will mitigate radium release to the surface. Additionally, the reclaimed sand  
11  
12 25 could have market value, and this could represent as much as a third of the cost savings. Tests  
13  
14 26 that employed the toxicity characteristic leaching protocol (TCLP) on these separated solids  
15  
16  
17 27 streams determined that this novel treatment diminished the risk of radium mobility for the  
18  
19 28 reclaimed sand, clays or disposed material, rendering them better suited for landfilling.

## 25 26 31 **Introduction**

27  
28 32 Environmental sustainability is one of eight millennium development goals put forward  
29  
30  
31 33 by the United Nations; and it remains one of the biggest challenges for the current generation.  
32  
33 34 Now, more than ever before, engineered solutions must be assessed through the lens of  
34  
35 35 environmental sustainability. Solutions to meet the increasing energy demand of a growing  
36  
37 36 population must be economically and environmentally sustainable. As our society transitions  
38  
39 37 from fossil fuels to cleaner and greener energy sources, natural gas has served as an important  
40  
41 38 bridge fuel toward sustainably renewable energy and a low-carbon future. This is because the  
42  
43 39 burning of natural gas yields about half to two-thirds as much carbon dioxide per unit of energy  
44  
45 40 generated, when compared to gasoline or coal <sup>1</sup>.

46  
47 41 Hydraulic fracturing has allowed for the extraction of natural gas from previously  
48  
49 42 uneconomic, low-permeability formations; and this opportunity has sparked an energy revolution  
50  
51 43 that is rapidly moving America towards energy independence <sup>2</sup>. However, this energy revolution  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 44 has not proceeded without controversy regarding issues around the relationship between  
4  
5 45 hydraulic fracturing and potential environmental impacts such as: waste solids landfilling, and  
6  
7 46 potential radioactivity exposure<sup>3</sup>, elevated methane concentrations and leakage along natural gas  
8  
9 47 distribution lines in urban centers<sup>4,5</sup>, greenhouse gas emissions of methane<sup>6-9</sup>, elevated salt  
10  
11 48 impacts on streams<sup>10-15</sup>, surface water impacts<sup>15-18</sup>, and associated health impacts<sup>19,20</sup>.  
12  
13  
14 49 Groundwater methane contamination from oil and gas activities has been investigated with  
15  
16 50 conflicting results: Osborn *et al.*<sup>21</sup> and Vengosh *et al.*<sup>18</sup> support this claim, while Molofsky *et al.*  
17  
18 51<sup>22</sup> and Siegel *et al.*<sup>23</sup> attribute this to natural geography. Herein, we address the first of these  
19  
20  
21 52 issues, namely, waste solids handling and management of radioactivity from hydraulic  
22  
23  
24 53 fracturing.

25  
26 54 The handling and treatment of hydraulic fracturing waste is challenging because the  
27  
28 55 liquid and solid wastes can contain elevated levels of naturally occurring radioactive material  
29  
30 56 (NORM) and high concentrations of salts<sup>24,25</sup>. Surface discharge of partially treated liquid  
31  
32  
33 57 wastes, including flowback and produced water, has led to increased levels of metals, chloride,  
34  
35 58 bromide and radioactivity in the receiving waters and sediments, as well as posing risks to  
36  
37 59 aquatic and human health<sup>10-12</sup>. These discharges are also linked with the possibility of  
38  
39  
40 60 generating disinfectant byproducts, which are possible carcinogens, in the drinking water  
41  
42 61 treatment facilities that are located further downstream<sup>14,15,26</sup>. Studies on the treatment of  
43  
44 62 produced water for NORM removal have included sulfate precipitation (as barium or strontium  
45  
46 63 sulfate) by sodium sulfate addition<sup>27-29</sup>, or by blending with acid mine drainage<sup>30-32</sup>; and ion  
47  
48  
49 64 exchange using strong acid resins<sup>33</sup>. Sulfate precipitation remains a very effective treatment for  
50  
51  
52 65 NORM removal from produced waters, however, sulfate addition results in the generation of  
53  
54 66 sludge enriched with NORM. Moreover, the dose of sulfate needed to precipitate barium (and

1  
2  
3 67 co-precipitated radium) is far greater with such high levels of salts – and consequently  
4  
5 68 suppressed activity coefficients – than would be needed if such precipitation was occurring in  
6  
7 69 freshwater that contained low salt levels<sup>29</sup>. Additionally, sulfate addition can result in scale  
8  
9 formation<sup>34</sup> and increased activity of sulfate reducing bacteria<sup>30</sup> when the fluid is reused for  
10  
11 70 hydraulic fracturing. While ion exchange can provide targeted radium removal, this process  
12  
13 71 would require pretreatment to reduce the competition for exchange sites offered by other divalent  
14  
15 72 cations.  
16  
17 73

18  
19 74 The authors herein are not aware of published research on reclaiming the solid materials  
20  
21 75 used in hydraulic fracturing, such as sand and clay, despite the considerable amounts of pristine  
22  
23 76 solids consumed by this industry. A sustainable energy future includes efforts to reduce wastes  
24  
25 77 that are landfilled, and strategies to recover valuable raw materials from wastes prior to disposal.  
26  
27 78 Silica sand is utilized as a proppant for extending the natural fractures and maintaining higher  
28  
29 79 permeability following hydraulic fracturing. The hydraulic fracturing of a single well can  
30  
31 80 consume as much as 5,000 tons of sand as proppant<sup>35</sup>. Currently, in Pennsylvania, fracturing  
32  
33 81 sands that return to the surface with flowback fluids and produced waters are disposed in  
34  
35 82 landfills. In 2011, about 15,000 tons of fracturing sand were reported disposed in landfills,  
36  
37 83 second after drill cuttings in disposal volume<sup>36</sup>. In that same year, 290 million liters (2.4 million  
38  
39 84 barrels) of drilling fluids, 1 billion liters (9 million barrels) of produced water, and 940 million  
40  
41 85 liters (7.9 million barrels) of flowback fluid were generated in Pennsylvania. Of that liquid  
42  
43 86 waste, 70% of drilling fluids were reused and 72% of the flowback fluid and brine were  
44  
45 87 reused/recycled in subsequent wells. However, we found no reported reuse/recycle of the  
46  
47 88 fracturing sands<sup>36</sup>.  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 89 The hydraulic fracturing industry has increased the demand for silica sand, and  
4  
5 90 consequently, sand's price has likewise increased from about \$40/ton to \$87/ton in a mere 10  
6  
7 91 years (dollar values adjusted to avg. 2017 USD)<sup>35</sup>. Most of the fracturing sand comes from the  
8  
9 92 Upper Midwest, especially Wisconsin – which in 2014 supplied almost 50% of all silica sand  
10  
11 93 used for hydraulic fracturing<sup>35</sup>. In 2013, silica sand accounted for 85% of all proppants (by  
12  
13 94 weight). This demand for sand affects other sand-using industries notably glass makers and iron  
14  
15 95 foundries, who extensively use the same fine-grained silica sand from the Upper Midwest<sup>35,37,38</sup>  
16  
17 96 (see **Figure S1**). Between 2003 and 2012, there was a 32% compound annual growth rate for  
18  
19 97 silica sand used for hydraulic fracturing, in that same period, the amount of sand used for other  
20  
21 98 non-fracturing uses dropped by an annual rate of 2.2%, further illustrating how the hydraulic  
22  
23 99 fracturing industry is a strong market force for silica sand<sup>35</sup>.

24  
25  
26  
27  
28 100 Economic, societal, and environmental issues related to sand mining and sand resources  
29  
30 101 are growing; and these pressures have been documented in reports on the diminishing sand  
31  
32 102 supply<sup>39</sup>, land disputes<sup>40</sup>, erosion caused by mining and transportation<sup>35</sup>, damage to local  
33  
34 103 ecosystems, increased risk of flooding<sup>41–43</sup>, and activist protests<sup>41,44,45</sup>. The Appalachian Basin,  
35  
36 104 of which the Marcellus Shale is a part, is the second most sand-consuming US basin<sup>46</sup> (following  
37  
38 105 the Eagle Ford and Woodbine Formation in the East Texas Basin.) The demand for sand is  
39  
40 106 expected to increase with the increased focus on developing the Marcellus Shale for natural gas  
41  
42 107 and gas liquids, as well as the anticipated increased drilling of an underlying Utica Shale  
43  
44 108 Formation<sup>35</sup>.

45  
46  
47  
48  
49 109 The increased drilling activity will not only lead to greater raw material use but also  
50  
51 110 greater waste volume generation. In Pennsylvania, as shown in **Figure S2**, landfills accepted  
52  
53 111 almost 7,000 tons of sludge from oil and gas wastewater treatment facilities in 2017. This sludge  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 112 contains radioactive material with typical  $^{226}\text{Ra}$  activities ranging from 0.111 Bq/g to 17.8 Bq/g  
4  
5 113 (3 pCi/g to 480 pCi/g)<sup>47,48</sup>. Research on the treatment of such technologically enhanced naturally  
6  
7 114 occurring radioactive materials (TENORM) sludge is limited<sup>48-50</sup>. Therefore, there is an  
8  
9 115 opportunity to evaluate raw material recovery and solid waste radioactive management for the  
10  
11 116 unconventional oil and gas industry.

12  
13  
14 117 Herein we propose to facilitate raw material recovery from unconventional oil and gas  
15  
16 118 residual solid wastes by employing a novel hydroacoustic cavitation system that can also include  
17  
18 119 advanced oxidation (HAC-AO). The HAC-AO system has been applied to the foundry and coal  
19  
20 120 industries for raw material recovery and waste reduction; and this has pointed the way to  
21  
22 121 diminished raw material use and significant savings to operating costs in both industries<sup>52-64</sup>.  
23  
24 122 Specifically, foundries that have implemented HAC-AO have been able to save tens of millions  
25  
26 123 of dollars over several decades, due to diminished sand, clay, and coal consumptions, lower air  
27  
28 124 pollution, and lower scrap metal use<sup>55,58,64</sup>. The system (**Figure 1**) utilizes cavitation to generate  
29  
30 125 localized cavities, which then collapse under ultrasonic inducement, resulting in high pressure –  
31  
32 126 reported to be as high as 172 MPa (1700 atm) – and temperature – as high as 4000-5000 °K, at  
33  
34 127 the nanoscale<sup>65-67</sup>. When the cavities are formed at the sand-clay-residue interfaces, this intense  
35  
36 128 collapse causes surface debris to be pried and sheared away from such solid surfaces as sand  
37  
38 129 grains, thus cleaning the sands<sup>68</sup>. At these localized regions, hydroxyl radicals are generated,  
39  
40 130 which react aggressively with organic compounds that are present on the solid surfaces or in  
41  
42 131 solution. Advanced oxidants, such as hydrogen peroxide and ozone, can be added into solution  
43  
44 132 so as to increase hydroxyl radicals generation<sup>69</sup>. HAC-AO technology causes disaggregation of  
45  
46 133 the waste particles by the dispersive energy released at bubble collapse, as well as the reactive  
47  
48 134 effects of the advanced oxidants. This HAC-AO system, which consists of a cavitation-inducing  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 135 chamber and ultrasonic generator, can be coupled with a hydrocyclone and a spiral concentrator  
4  
5 136 to first disaggregate sands from clays and silts, and then separate these three from one another  
6  
7  
8 137 **(Figure 1)**.

9  
10 138 In a recent publication, the underlying mechanism for HAC-AO was studied by  
11  
12 139 nanoscale Surface Imaging Spectroscopy (SIS)<sup>68</sup>. The SIS technique provided evidence for the  
13  
14 140 separation mechanism of HAC-AO, as the microscopic cleaning process for the removal of  
15  
16  
17 141 asphalt from a glass surface was observed. This study demonstrated the principles that cause the  
18  
19 142 separation of sand grains from spent foundry residues.

20  
21 143 The goal of this work was to reclaim hydraulic fracturing raw materials, while reducing  
22  
23 144 landfill wastes and mitigating possible exposure to natural radium in the wastes. There were  
24  
25  
26 145 three objectives of this research. 1) To appraise a novel approach for reclaiming sand from  
27  
28 146 hydraulic fracturing waste using HAC or HAC-AO, so as to reduce the volume of solid material  
29  
30 147 that is disposed in landfills; 2) to evaluate the resulting radioactivity of the sands and clays that  
31  
32 148 have been separated out of the waste materials following HAC or HAC-AO treatment, including  
33  
34 149 leachability in a simulated landfill environment; and 3) to explore the radium affiliation within  
35  
36  
37 150 hydraulic fracturing solid materials. The hypothesis was that hydroacoustic cavitation (and/or  
38  
39 151 HAC-AO) would disaggregate fine material (clays) from large grain material (sand); and  
40  
41  
42 152 following this disaggregation, physical separation devices could then create a distinct stream of  
43  
44 153 recoverable, cleaned sand. As a consequence of this particle separation, we expected that higher  
45  
46  
47 154 radium activities would become affiliated with the clay-sized fractions (including dried salts and  
48  
49 155 organic surfactants that could be separated from the clays); whereas lower radium activities  
50  
51 156 would become affiliated with sand-sized fractions.

## 157 **Materials and Methods**

### 158 *Sample Collection*

159 Representative dewatered residual solid waste was collected in ~20 liters (5 gal) buckets  
160 from a hydraulic fracturing, residual waste-processing facility located in Pennsylvania. The  
161 buckets were transferred to laboratories at the Pennsylvania State University and stored at room  
162 temperature prior to testing. The water content of the residual waste was 53% by weight as  
163 determined gravimetrically and in triplicate from multiple well-mixed buckets.

### 164 *Size Classification*

165 Size classification was determined using USA standard testing sieve ASTM E-11  
166 specification by WS Tyler Incorporated. The solids were size-classified by wet sieving through  
167 US sieve mesh #70 through #230 (212  $\mu\text{m}$  to 63  $\mu\text{m}$ ), and immediately dried overnight in a  
168 105 °C convection oven, after which the dry weights were recorded. All grains smaller than  
169 63  $\mu\text{m}$ , along with the wet-sieving water, were dried in the bottom pan; and this fraction thus  
170 contained some dissolved salts and organics. The samples were put into three bins based on size:  
171 +70 mesh, i.e. material retained on the #70 sieve; -70+230 mesh, i.e. material that passed through  
172 the #70 sieve but not the #230 sieve; and -230 mesh, i.e. material that passed through the #230  
173 sieve. For simplification in discussion, material greater than sieve size #70 (+70 mesh i.e. > 212  
174  $\mu\text{m}$ ) is referred to as “sand”, and material less than sieve size #230 (-230 mesh i.e. <63  $\mu\text{m}$ ) is  
175 referred to as “clay” per ASTM D6913-04 [62]. Material between those two size fractions is  
176 referred to here as “silt”.

### 177 *Hydroacoustic Cavitation System*

178 We employed a pilot-scale system that included hydroacoustic cavitation, which could be  
179 coupled with advanced oxidation (herein identified as “HAC-AO”). This system was developed

1  
2  
3 180 by Furness-Newburge, Inc. (Versailles, KY). Its components are scaled to pilot size and are  
4  
5 181 similar to those used in industrial and sand reclaim systems as adapted under the registered  
6  
7 182 trademark names of Sonoperoxone® and Pneucol®; and these modular components can be put in  
8  
9 183 parallel to treat greater masses, up to 2 tons per hour. The system circuit was as shown in **Figure**  
10  
11 184 **1**. The system has been used by previous Penn State researchers: Liu *et al.* (2017)<sup>61</sup> and Barry *et*  
12  
13 185 *al.* 2015 and 2017<sup>62,63</sup>. The hydrocyclone and spiral used in these tests had been previously used  
14  
15 186 by Benusa and Klima (2009)<sup>70</sup>. The HAC-AO system consists of a 227 L (60 gal) polyethylene  
16  
17 187 conical “*feed*” tank (61 cm diameter and 107 cm height [24” diameter and 42” height]), a 5 HP  
18  
19 188 centrifugal pump (3450 RPM) with Bluffon fixed-speed motor, a 11.43 cm to 15.24 cm (4.5 in  
20  
21 189 by 6 in) ID and 16.51 cm (6.5 in) OD stainless steel ultrasonic chamber controlled by an  
22  
23 190 ultrasonic generator operating nominally at 25 kHz with an automatic frequency control unit, and  
24  
25 191 a cavitation chamber designed to cause hydrodynamic cavitation within the flow field of passing  
26  
27 192 fluid. The circuit was piped with 3.81 cm (1.5 in) diameter PVC schedule 80 piping. Three way  
28  
29 193 valves along the circuit enabled flow to be in the recirculation mode (without cavitation or  
30  
31 194 ultrasonics) or in operation mode (with cavitation and ultrasonics).  
32  
33  
34  
35  
36  
37

38 **FIG. 1.**

39  
40 196 The hydroacoustic cavitation circuit was then connected to a Krebs urethane  
41  
42 197 hydrocyclone (MOD U4-in-10°) with inlet pressure of 103 kPa (15 psi). The hydrocyclone is a  
43  
44 198 device used for size separations on a slurry stream. The slurry was fed tangentially via the inlet.  
45  
46 199 As the slurry flowed through the hydrocyclone, centrifugal forces caused coarse particles to  
47  
48 200 migrate to the wall of the hydrocyclone and out through the bottom. This material was classified  
49  
50 201 as the “*underflow*”. Meanwhile, a counter vortex pushed finer particles along with the bulk of  
51  
52 202 the water up through the top vortex. This material was classified as the “*overflow*”. By the  
53  
54 203 principles of the hydrocyclone, the overflow will host a lower percent of solids, smaller particle  
55  
56  
57  
58  
59  
60

1  
2  
3 204 sizes, and larger flow rates, while the underflow will have a high solids percent, larger particle  
4  
5 205 sizes, and lower flow rates. After separation by the hydrocyclone, the spiral concentrator was  
6  
7 206 deployed to further separate the solids. A Multotex SX7 single-start two-stage seven-turn spiral  
8  
9 207 concentrator was used. The spiral was operated as a closed-circuit consisting of a 5.08 cm by  
10  
11 208 3.81 cm (2 in by 1.5 in) centrifugal pump (Ash, MOD 5 ME), 15 HP motor (Westinghouse, 460  
12  
13 209 V, 1760 rpm) with variable frequency controller (ABB), and 378 L (100 gal) stainless steel  
14  
15 210 sump. The spiral concentrator operated by gravity separation as the slurry flowed along the  
16  
17 211 descending spiral trough. Low density particles were forced to migrate to the outer perimeter,  
18  
19 212 while high-density particles migrated to the inner perimeter. After four turns, the most-dense  
20  
21 213 materials were diverted into the center column, while the remaining slurry continued to flow  
22  
23 214 down the trough. The splitter box, located at the end of the trough, partitioned the slurry into six  
24  
25 215 streams or ports. Samples were collected at this point from each of the spiral “ports”. For these  
26  
27 216 tests, fines were concentrated to the inner ports (1-3), while coarse-grained material was at the  
28  
29 217 outer ports (4-6). The densest particles, were rejected from the first stage through the center  
30  
31 218 column (port 7).

### 32 33 219 *Pilot Scale Experimental Methods*

34  
35  
36  
37  
38 220 The residual solids were mixed with University Park municipal tap water to prepare a 5%  
39  
40 221 solids slurry, and then this slurry was sieved through US #16 mesh (1.2 mm). This tap water  
41  
42 222 source was used because of its convenience at our pilot plant, and hosted negligible radium. The  
43  
44 223 sieving removed grains that could otherwise clog the pump impellers; and few grains were found  
45  
46 224 larger than 1.2mm. This slurry was introduced into the 50-gallon “feed” tank (**Figure 1**). The  
47  
48 225 HAC-AO system was run as a pseudo-batch reactor: flow was recirculated from the feed tank,  
49  
50 226 bypassing the cavitation box through the hydroacoustic chamber and back to the feed tank to  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 227 homogenize the material. This recirculation was done with hydroacoustic cavitation turned off.  
4  
5 228 After about 2 minutes of homogenizing the material, the components of interest for each run  
6  
7 229 were turned on and the system operated for 10 minutes. After this 10 minute operation, the flow  
8  
9 230 was diverted to the hydroclone, where the “underflow” and “overflow” were collected in ~20 L  
10  
11 231 (5 gal) buckets and a ~200 L (55 gal) drum. The overflow and underflow material were  
12  
13 232 separately processed through the spiral concentrator. For each run, samples were collected from  
14  
15 233 the feed tank, underflow, overflow and spiral outlet ports (see **Figure 1**). These samples were  
16  
17 234 then size-classified as described above. The following experimental conditions were chosen to  
18  
19 235 test the hypothesis:

- 20  
21  
22  
23  
24 236 1. No HAC Control: This was the Control run. The slurry was not sent through the  
25  
26 237 cavitation box and the ultrasonics unit was not operating. Recirculation proceeded for 10  
27  
28 238 minutes before passing the slurry through the hydrocyclone.
- 29  
30  
31 239 2. HAC: Hydroacoustic cavitation was implemented (without ozone or hydrogen peroxide).  
32  
33 240 The slurry was sent through the cavitation box and the ultrasonic unit was operating at  
34  
35 241 100% frequency power. Recirculation proceeded for 10 minutes before passing the slurry  
36  
37 242 through the hydrocyclone.

38  
39  
40 243 Additionally, two conditions were included for further analysis to evaluate the  
41  
42 244 redistribution of radium. These were:

- 43  
44  
45 245 3. HAC-AO: Hydroacoustic cavitation coupled with advanced oxidation (AO - hydrogen  
46  
47 246 peroxide, at a dose of 0.1% (1,000 mg/L), and near-saturated ozone (at a rate of 566 L/m  
48  
49 247 (20 SCFM) from an oxygen-to-ozone system). Based on prior trials, this H<sub>2</sub>O<sub>2</sub> plus ozone  
50  
51 248 dose in freshwater was found to generate about 0.5 – 1 mg/L of OH\* radical <sup>71</sup>.

1  
2  
3 249 4. HAC-LR: Hydroacoustic cavitation (no AO) for a longer run (LR) of 30 minutes  
4  
5 250 operation as opposed to 10 minutes. We conducted limited tests with HAC-LR.  
6  
7 251 Representative samples from these additional runs provided further insight into the effect  
8  
9  
10 252 of HAC-AO or HAC-LR on radium management and will be further discussed.

11  
12 253 We also collected an “As received” solid sample, which was directly sampled from  
13  
14 254 multiple representative and well mixed ~20 L (5 gal) buckets. To collect a “feed” sample, we  
15  
16 255 passed the 5% slurry around the recirculation loop (without HAC or AO) for 2 minutes, to  
17  
18 256 achieve a uniform mix, and then collected the slurry sample from the recirculation outlet at the  
19  
20 257 feed tank.

#### 21 22 258 *Toxicity Characteristic Leaching Procedure*

23  
24 259 The EPA Method 1311 Toxicity Characteristic Leaching Procedure (TCLP)<sup>72</sup> evaluated  
25  
26 260 the mobility of <sup>226</sup>Ra and inorganic cations from the treated solids after HAC-AO, HAC, or the  
27  
28 261 Control treatment. The TCLP is intended to mimic the chemical conditions of a landfill  
29  
30 262 environment. The extraction fluid (fluid #2 – 5.7 mL glacial acetic acid diluted to a volume of 1  
31  
32 263 L using reagent water) was mixed with solid samples at a 20:1 fluid-solid mass ratio in 250 mL  
33  
34 264 Nalgene® polypropylene flat bottom centrifuge tubes. After mixing for 18 hours, the suspension  
35  
36 265 was centrifuged on an Eppendorf 5810R centrifuge at 3,000 RPM for 10 minutes. The  
37  
38 266 supernatant was filtered through a 0.7 μm TCLP glass fiber filter (Pall Laboratory) and then  
39  
40 267 transferred to a 50 mL test tube, acidified to <pH 2 with concentrated nitric acid, and stored at  
41  
42 268 4 °C until analyses using inductively coupled plasma atomic emission spectrophotometry (ICP-  
43  
44 269 AES). The solid residue was then dried and the <sup>226</sup>Ra activity of this solid was determined by  
45  
46 270 gamma spectroscopy (see description below).

#### 47 48 271 *Sequential Extractions*

1  
2  
3 272 Radium (and major metal) association in the size-classified solids was determined by a  
4  
5 273 four step sequential extraction procedure that we modified from <sup>73</sup> and <sup>74</sup>. The extractions were  
6  
7 274 performed at a 20:1 fluid-to-solid mass ratio in which the extraction fluids were chosen to  
8  
9 275 determine radium association with salts/evaporated pore water (Step 1: distilled–deionized water  
10  
11 276 for 24 hours); with surface sites (Step 2: 1M ammonium acetate for 12 hours); with carbonate  
12  
13 277 minerals (Step 3: 9% acetic acid for 12 hours); and with metal oxides (Step 4: 0.1M hydrochloric  
14  
15 278 acid for 12 hours) (see **Table 1**). The initial <sup>226</sup>Ra activity, prior to Step 1 extraction, of the “As  
16  
17 279 received” solids, or wet sieved, size-classified treated solids was classified as Step 0. It is noted  
18  
19 280 that none of these extraction steps would dissolve barium sulfate.  
20  
21  
22

23  
24 281 The sequential extractions were carried out in 250 mL Nalgene® polypropylene flat  
25  
26 282 bottom centrifuge tubes. After each extraction, the suspensions were centrifuged on an  
27  
28 283 Eppendorf 5810R centrifuge at 3,000 RPM for 10 minutes, and then decanted. The pelletized  
29  
30 284 solids were then rinsed with distilled-deionized water at about two-thirds the volume of the  
31  
32 285 extraction fluid. All rinsates and supernatants were combined, filtered through a 0.7  $\mu\text{m}$  TCLP  
33  
34 286 glass fiber filter (Pall Laboratory), transferred to 50 mL test tubes, acidified to <pH 2 with  
35  
36 287 concentrated nitric acid, and then refrigerated at 4 °C until ICP-AES analyses. The resulting  
37  
38 288 pellets were oven-dried and <sup>226</sup>Ra activity in the solid was determined by gamma spectroscopy  
39  
40 289 (as described below).  
41  
42  
43

#### 44 290 **Table 1.**

##### 45 291 *Major Metals Analyses*

46  
47 292 Elemental compositions of the acidified supernatants (Li, Na, K, Mg, Ca, Sr, Ba, Mn, Fe,  
48  
49 293 and Al) were determined using ICP-AES on a Perkin-Elmer Optima 5300DV optical Emission  
50  
51 294 Spectrometer per EPA standard 200.7.  
52  
53

##### 54 295 *Radium Analysis*

1  
2  
3 296 Radium-226 activities of all solid samples were determined by gamma spectroscopy on a  
4  
5 297 Canberra ultra-low background small anode germanium (SAGe) well detector, after the  
6  
7 298 incubation period of three weeks. The reported  $^{226}\text{Ra}$  activity was the average of the daughter  
8  
9 299 products activities ( $^{214}\text{Bi}$  at 295.2 keV and 351.9 keV,  $^{214}\text{Po}$  at 609.3 keV). The standard error  
10  
11 300 was reported and the error calculation is included in the ESI. The sample geometry used was a  
12  
13 301 Wheaton 24 mL poly seal cone-lined urea capped HDPE liquid scintillation vial with counting  
14  
15 302 efficiencies determined using the certified UTS-2 uranium tailings provided by the Canadian  
16  
17 303 Certified Reference Materials Project (CCRMP). The efficiencies of the samples were corrected  
18  
19 304 for height and density, as these factors could otherwise cause a 5-40% affect in apparent  $^{226}\text{Ra}$   
20  
21 305 activities. We monitored  $^{226}\text{Ra}$  because it is the prominent radioactive parent in unconventional  
22  
23 306 oil and gas wastes and its long half-life (1600 years) makes it persistent in the environment.  
24  
25 307 Because radium's isotopes are chemically identical, the results presented for  $^{226}\text{Ra}$  should be  
26  
27 308 consistent for  $^{228}\text{Ra}$  <sup>75,76</sup>. Sample masses ranged from 5 g to 35 g. To control for mass, we  
28  
29 309 counted our standards within similar masses of 8g to 40 g, and develop a regression for the  
30  
31 310 efficiencies at the varying masses we encountered. Counting time ranged from a few hours to a  
32  
33 311 few days, because data collection was terminated either when the counting error was lower than  
34  
35 312 5% or counting time had exceeded 48 hrs. with insignificant counts. Most samples were counted  
36  
37 313 once. Representative samples were tested in triplicate, and found to be within 1 – 3% of one  
38  
39 314 another.

### 315 *Materials*

316 All analytical chemicals were reagent grade and supplied by VWR. Distilled de-ionized  
317 water was provided by the ThermoScientific Barnstead Nanopure water system with resistivity at  
318 18.2  $m\Omega$ . The extraction fluids for the toxicity characteristic leaching procedure and sequential

1  
2  
3 319 extractions were stored in glass Pyrex bottles at room temperature. Optical light microscope  
4  
5 320 images were acquired on a Zeiss Axiophot microscope.  
6  
7

## 8 321 **Results**

### 9 10 322 *Pilot Scale Trials for Raw Material Recovery*

11  
12 323 We conducted grain size analysis of the treated solids that were recovered at the “feed”  
13  
14 324 tank, “overflow”, “underflow”, and the “spiral ports” (**Figures 2A – 2F**). In this figure, fine  
15  
16 325 particle streams will plot high and to the left, while coarse particle streams will plot low and to  
17  
18 326 the right. In the No HAC Control run (**Figure 2D**), the overflow and underflow overlap –  
19  
20 327 showing that the two streams had very similar particle sizes because no disaggregation had  
21  
22 328 occurred. When HAC was applied (**Figure 2A**), particle disaggregation occurred – the clays  
23  
24 329 were separated from the sand and the hydrocyclone successfully created two distinct streams of  
25  
26 330 clay versus sand. The material collected from the overflow has plotted higher than the material  
27  
28 331 collected from the underflow, indicating finer grain size in the overflow than the underflow, with  
29  
30 332 both streams having distinct particle sizes from the feed material that entered the system.  
31  
32

### 33 333 **FIG. 2.**

34  
35  
36 334 In our Control run (No HAC), there was no particle disaggregation, and thus no  
37  
38 335 subsequent physical separation was observed in the spiral effluents (ports 1 and 2) when  
39  
40 336 processing the overflow (**Figure 2E**). Likewise, there was little physical separation observed in  
41  
42 337 the spiral port 7 when processing the underflow (**Figure 2F**). In contrast, when the solids were  
43  
44 338 treated with HAC, the physical separation devices successfully separated the disaggregated  
45  
46 339 solids into a clay-rich stream that discharged from the overflow versus a sand-rich stream that  
47  
48 340 discharged from the underflow (**Figure 2A**). Moreover, when the overflow was passed through  
49  
50 341 the spiral, a clay-rich stream could be gleaned from ports 1 and 2 (**Figure 2B**), and when the  
51  
52 342 underflow was passed through the spiral, a sand-rich stream could be gleaned from ports 3 and 7  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 343 (**Figure 2C**). Indeed, HAC treatment (even without AO) resulted in a particle stream from the  
4  
5 344 overflow that was 82% – 88% “clays” ( $< 63 \mu\text{m}$ ) through ports 1 and 2; and these ports  
6  
7 345 constituted about 90% of all the overflow solids. Furthermore, the particle stream following  
8  
9 346 HAC from the underflow was as high as 76% “sand” ( $> 210 \mu\text{m}$ ) through port 7 and 51% through  
10  
11 347 port 3 (**Figure S3**); and these ports constituted about 72% of all underflow solids. Thus, the  
12  
13 348 HAC-hydrocyclone-spiral unit operations could offer a means for recovering these raw materials.  
14  
15 349 With HAC-AO, the sand recovery from port 7 was 61%. Without HAC, the control offered only  
16  
17 350 slight separation of sizes (**Figure S3**).

18  
19 351 The mass balance-normalized recovery of raw materials is shown in **Table 2**. The  
20  
21 352 recovery of sand through ports 3 and 7 was ~38% when treated with HAC versus only 3% for the  
22  
23 353 Control – No HAC. The recovery of clays through ports 1 and 2 was ~15% when treated with  
24  
25 354 HAC versus ~10% for the Control – No HAC. Without HAC treatment, the underflow contained  
26  
27 355 36% clay; compared to only 20% when treated with HAC.

28  
29 356 **Table 2.**

30  
31 357 **FIG. 3.**

32  
33 358 Optical microscope images provided a visual assessment of the performance of these  
34  
35 359 treatments. **Figure 3** shows the HAC-treated reclaimed sand (underflow port 7) as compared to  
36  
37 360 the untreated, as-received material. As shown, the disaggregating effect of HAC treatment  
38  
39 361 removed the adhered/aggregated clay particles, and yielded clean, clear sand grains. The control,  
40  
41 362 without HAC, yielded grains that looked much like the “As received” material (photo not shown  
42  
43 363 herein).

44  
45 364 *Toxicity Characteristic Leaching Protocol (TCLP)*

46  
47 365 The mobility of major elements and radioactivity of the selected size-classified solid  
48  
49 366 waste samples was assessed using the TCLP to investigate whether HAC treatment increased the

1  
2  
3 367 leachability of these elements from the residual solid waste material (**Figures 4 & 5**). These  
4  
5 368 results showed that radium did not leach from any of the samples, except for the “As received”  
6  
7 369 clays (**Figure 4**). For all other cases, radium activities of the treated solids remained the same  
8  
9 370 before and after the TCLP extraction. This indicated that there would be less risk of radium  
10  
11 371 leaching from solids following treatment by HAC or HAC-AO than for solid materials that  
12  
13 372 received no treatment.  
14

15  
16  
17 **FIG. 4.**

18  
19 374 We also monitored the mobility of several major elements (Li, Na, K, Mg, Ca, Sr, Ba,  
20  
21 375 and Mn) that could be leached from these solids during the TCLP extraction (**Figure 5**).  
22  
23 376 Although iron and aluminum were also monitored, their concentrations were always below  
24  
25 377 detection. Barium leached extensively from the “As received” material, and especially from the  
26  
27 378 “As received” clays, but it did not leach significantly from any of the treated solid samples.  
28  
29 379 Strontium, sodium, lithium and potassium leached the most from the “As received” and “feed”  
30  
31 380 samples, and from the No HAC overflow. Calcium and magnesium leached from many of the  
32  
33 381 treated samples.  
34  
35

36  
37 382 When comparing **Figure 4** with **Figure 5**, we observed that radium mobility strongly  
38  
39 383 followed barium mobility. Specifically, the TCLP extracted both radium and barium from the  
40  
41 384 “As received” clays; but following treatment, the TCLP extracted minimal amounts of radium or  
42  
43 385 barium.  
44

45  
46 386 Following any of these HAC or HAC-AO treatments, the barium concentration in the  
47  
48 387 extractants was 0.8 mg/L to 2 mg/L (**Table S1**), compared to levels of 2 to 13.5 mg/L for the No-  
49  
50 388 HAC Control. Notably, all these extractant levels following treatment were far below the TCLP  
51  
52 389 regulatory limit of 500 mg/L. The concentrations of the other metals in the extractants from the  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 390 treated solids were all less than 5 mg/L, indicating that there was little potential for leaching  
4  
5 391 from HAC-treated materials.

7  
8 392 **FIG. 5.**

9  
10 393 *Sequential Extractions*

11  
12 394 Radium and major metal associations in the size-classified solids were determined by a  
13  
14 395 four step sequential extraction procedure modified from <sup>73,77</sup> and <sup>74</sup> (**Figures 6 & 7**). These  
15  
16 396 samples were selected to represent recoverable sand (sand fraction from underflow port 7),  
17  
18 397 recoverable clay (clay fraction from overflow port 1), and the intermediate silts that would be  
19  
20 398 disposed (silt fraction from underflow).

21  
22  
23  
24 399 **FIG. 6.**

25  
26 400 For all size fractions, considerable radium was leached during step 4 – and to a lesser  
27  
28 401 extent during step 3 (**Figure 6**). The cations that leached most during step 4 were Ba, Sr, Fe, and  
29  
30 402 Al (**Figure 7**), indicating that radium was likely associated with their oxides. During step 3, it  
31  
32 403 was the Ca, Mg, and Fe-carbonates that could be extracted – along with some radium that was  
33  
34 404 associated with these carbonates. For the “As received” samples from each size-classification,  
35  
36 405 the barium leached far more during steps 2, 3, and 4 than barium leached from the treated  
37  
38 406 samples (**Figure 7**).

39  
40  
41  
42 407 Sequential extractions of the reclaimable sand (underflow port 7), revealed minimal  
43  
44 408 radium leaching during steps 1 and 2 when HAC or HAC-AO was applied; and more radium  
45  
46 409 leached during steps 3 and 4 – indicating that in the sand matrix, radium was associated with  
47  
48 410 carbonate and oxide minerals (**Figure 6**). When HAC or HAC-AO was employed, the  
49  
50 411 reclaimable sands had <sup>226</sup>Ra activities of ~0.74 Bq/g (20 pCi/g). Parenthetically, when HAC was  
51  
52 412 operated for an extended time of 30 minutes (i.e. HAC-LR), the sand from this underflow had  
53  
54 413 <sup>226</sup>Ra activities of 0.207 Bq/g (5.6 pCi/g) (**Figure S4**). Thus, the HAC-LR process could yield a

1  
2  
3 414 reclaimable sand that hosted low radium levels. Major metal mobility showed that calcium,  
4  
5 415 magnesium, and iron were also greatly leached by step 3 (**Figure 7**). This infers that there could  
6  
7 416 be some carbonate minerals in the sand-size particles leaching calcium, magnesium, iron, and  
8  
9 417 aluminum. Step 4 leached barium, iron, and aluminum – inferring the presence of these oxides  
10  
11 418 (**Figure 7**).

12  
13  
14 419 **FIG. 7.**

15  
16 420 **FIG. 8.**

17  
18 421 For all the clay fractions, the first extraction step (DI water) diminished radium activity,  
19  
20 422 indicating that a substantial portion of the radium in these clay-sized fractions was affiliated with  
21  
22 423 dissolvable salts and/or organic surfactants (**Figure 6**). Particularly, relative to the overflow port  
23  
24 424 1 “clays”, organic surfactants, with their 0.85 – 0.95 mg/L density, would be expected to  
25  
26 425 congregate at port 1. When the sequential extraction results (**Figure 6**) are overlapped with the  
27  
28 426 major metals leached (**Figure 7**), it appears that radium was associated (at least in part) with  
29  
30 427 strontium, lithium, sodium, and potassium salts (step 1); with calcium, magnesium, iron, and  
31  
32 428 aluminum carbonates (step 3); and with strontium and iron oxides (step 4). Amongst these clay-  
33  
34 429 rich samples, there was limited radium leaching after step 2, indicating again that radium was not  
35  
36 430 associated with surface sites or low-charge clay interlayer sites.

37  
38 431 We also monitored the mass loss that occurred during each extraction (**Figure 8**). While  
39  
40 432 the dissolution of carbonate minerals during step 3 accounted for the greatest mass loss (**Figure**  
41  
42 433 **8**), radium did not follow this trend, as step 1 accounted for the greatest radium leaching. This is  
43  
44 434 suggestive that radium association with the clays was not by interlayer adsorption but instead,  
45  
46 435 radium was associated with the dried salts that had precipitated out of solution during the drying  
47  
48 436 process after wet sieving – and also possibly with organic surfactants.

1  
2  
3 437 Finally, for the silts (underflow) that we presume will be disposed, sequential extractions  
4  
5 438 showed that radium was not made more mobile following HAC-AO treatment compared to the  
6  
7  
8 439 Control samples. Although a greater portion of this HAC-AO silt fraction contained oxides (step  
9  
10 440 4) (**Figure 8**) – possibly strontium, iron, and aluminum oxides (**Figure 7**) – radium was not  
11  
12 441 released during their dissolution. Metal mobility also showed the presence of calcium,  
13  
14 442 magnesium, iron, and aluminum carbonates (step 3) (**Figure 7**). However, none of the treatments  
15  
16 443 rendered radium more readily leachable from the silts.  
17  
18

#### 19 444 **Discussion**

20  
21 445 *Raw material recovery: HAC treatment resulted in the disaggregation of residual solids,*  
22  
23 446 *allowing for sand and clay separation*  
24  
25

26 447 The market for hydraulic fracturing sand continues to grow as increased drilling activity,  
27  
28 448 greater sand demand and a globally diminishing supply of suitable sand drive prices higher. It is  
29  
30 449 becoming necessary to seek out alternative sources for raw materials. The quality of sand used as  
31  
32 450 hydraulic fracturing proppant is specified by the API RP 19C/ISO 13503-2 standard<sup>78</sup>. The  
33  
34 451 standard includes specifications for particle size, roundness and sphericity, among others. The  
35  
36 452 HAC treatment herein resulted in the recovery of sand particles that had properties consistent  
37  
38 453 with those required by the API standard. The reclaimed sand grains herein were all retained on  
39  
40 454 the US #70 sieve sizes and hence could be utilized as 40/70 proppant (i.e. sand between #40 and  
41  
42 455 #70 sieves). Optical microscope images revealed that these sand grains also had similar  
43  
44 456 roundness and sphericity as required by the API standard. In addition, when HAC treatment was  
45  
46 457 applied for 30 minutes, the radium activity on the sand grains could be as low as 0.207 Bq/g (5.6  
47  
48 458 pCi/g), which offers a reduced risk for worker exposure to radioactivity. The HAC treatment of  
49  
50 459 the residual waste also resulted in the concentration of fine clays. These clays (and dried  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 460 salts/organic surfactants) were found to have high radium activities, as high as 1.85 – 3.7 Bq/g  
4  
5 461 (50 – 100 pCi/g). However, more than half of the radium in these dried solids was associated  
6  
7 462 with salts or organic surfactants, and was mobilized when the dried solids were suspended in DI  
8  
9 463 water. These salts and surfactants could be returned back downhole with the hydraulic  
10  
11 464 stimulation fluid; and they would thus not end up with landfilled solids.  
12  
13

14 465 We anticipate that by passing the underflow material through the HAC or HAC-AO  
15  
16 466 systems a second time, we could achieve even more sand and clay recovery, as the underflow  
17  
18 467 following one pass still contained 20% clays by mass when size fractioned (**Table 2**). While  
19  
20 468 these clays are not presently of market value, the accumulation of radium presents an opportunity  
21  
22 469 to revise the current management practices for radioactive residual waste.  
23  
24

25 470 Assuming a waste generation of 5,000 tons per year from such a facility as encountered  
26  
27 471 by this work, HAC treatment can result in the generation of marketable source sand that could be  
28  
29 472 valued around \$40,000 to \$80,000 per year, when sold at a fraction of the price of freshly mined  
30  
31 473 sand (**Table 3**). This value can be 3 to 5 times greater if resin coated sands or ceramic proppant  
32  
33 474 have been used<sup>79</sup>. In 2017, 6,700 tons of residual sludge waste from facilities treating oil and gas  
34  
35 475 wastewater was recorded as being disposed in PA landfills (**Figure S2**). The reduction in sludge  
36  
37 476 waste volume as a result of sand and clay reclamation with treatment via HAC could reduce  
38  
39 477 landfill costs by about \$100,000 to \$300,000 per year in Pennsylvania. This is a significant cost  
40  
41 478 savings for waste management operations.  
42  
43  
44

45  
46  
47 **Table 3.**

48  
49 480 *Radium associations in the residual solids: HAC treatment diminished radium and barium*  
50  
51 481 *mobility*  
52

53 482 The combination of the modified TCLP and sequential extractions gave insights into  
54  
55 483 radium mobility and radium association in the HAC-treated residual waste solids. Firstly,  
56  
57  
58  
59  
60

1  
2  
3 484 without treatment, the clay-sized particles ( $<63\mu\text{m}$ ) showed unfavorably high potential for losing  
4  
5 485 radium and barium through leaching in the landfill. After HAC-treatment, this potential was  
6  
7 486 dramatically and consistently reduced for both radium and barium. Additionally, the silt-sized  
8  
9  
10 487 (between  $63\mu\text{m}$  and  $210\mu\text{m}$ ) and sand-sized particles ( $>210\mu\text{m}$ ), did not show potential for  
11  
12 488 leaching radium or barium following HAC or HAC-AO treatments. Radium associations in the  
13  
14  
15 489 residual waste before treatment indicated that radium was most mobile from the particle sizes  
16  
17 490 less than  $63\mu\text{m}$  and should be further evaluated prior to disposal.

18  
19 491 An interesting finding was that radium was removed during step 1 of the sequential  
20  
21 492 extractions, and thus perceived as being associated with dried salts or organic surfactants in this  
22  
23 493 residual waste. This residual waste was collected from a facility that does not treat the  
24  
25  
26 494 wastewater with sulfate addition for radium control. There are a number of such facilities with  
27  
28 495 similar operations that handle oil and gas waste. The residual solids coming from such facilities  
29  
30  
31 496 are likely to have similar radium associations.

32  
33 497 It is possible that radium was complexed with organic compounds in this material. Such  
34  
35 498 compounds could be surfactants, acetate, and EDTA. These (and especially surfactants) are used  
36  
37 499 during hydraulic fracturing; and they have been detected in flowback and produced water<sup>25,81,82</sup>.  
38  
39  
40 500 We observed the presence of organics (enough to form a surface sheen) in the waste and slurry  
41  
42 501 used in the HAC treatment; and this would be indicative that surfactants are present. Moreover,  
43  
44 502 the combination of cavitation and bubbled ozone resulted in dissolved air that accumulated in the  
45  
46  
47 503 ultrasonic chamber, and apparently created a similar phenomenon as for a small-scale dissolved-  
48  
49 504 air flotation unit. This resulted in the agglomeration of an organic-rich clay in samples collected  
50  
51 505 from HAC and especially HAC-AO treatments. As these samples dried, we infer that the radium  
52  
53  
54 506 that had been complexed by these organic compounds became associated with the clays. The

1  
2  
3 507 operation of the HAC system would have caused these organic-rich clays to be concentrated in  
4  
5 508 the overflow and subsequently in spiral ports 1 and 2. This could be an explanation of the very  
6  
7 509 high radium activity found in the clays from HAC-AO overflow port 1. The sequential extraction  
8  
9 510 of these clays showed radium mobility following the first step (DI water). Our prior research  
10  
11 511 with foundry green sand indicated that HAC-AO released organic residues from solid surfaces  
12  
13 512 <sup>56,68</sup>. Thus, such radium-rich organic compounds, as well as salts, could be separated from the  
14  
15 513 clays, and returned back downhole with hydraulic stimulation fluids. We note that the chemical  
16  
17 514 oxygen demand (COD) of the extractant following this step was determined to be 1,300 mg/L;  
18  
19 515 indicating that indeed anionic organic surfactants, which are known to complex cationic radium  
20  
21 516 <sup>83</sup>, could in part explain the mobility of radium. In overview, the combination of radium  
22  
23 517 association with salts and organics presents an opportunity for the development of new radium  
24  
25 518 management practices of such residual solids.

### 30 519 *Implications for disposal*

31  
32  
33 520 The Pennsylvania Department of Environmental Protection (PA DEP) commissioned a  
34  
35 521 study to investigate exposure and contamination risks from TENORM at facilities impacted by  
36  
37 522 oil and gas operations <sup>47</sup>. The average radium activity reported by this PA DEP study for  
38  
39 523 proppant sand prior to hydraulic fracturing was  $8.99 \text{ Bq/kg} \pm 2.18$  ( $243 \text{ pCi/kg} \pm 59$ ), and after  
40  
41 524 was  $128 \text{ Bq/kg} \pm 110$  ( $3460 \text{ pCi/kg} \pm 2990$ ); while the filter cake (i.e., sludge) of nine zero  
42  
43 525 liquid discharge facilities had activities that ranged from  $0.111 \text{ Bq/g}$  to  $17.8 \text{ Bq/g}$  ( $3 \text{ pCi/g}$  to  $480$   
44  
45 526  $\text{pCi/g}$ ) <sup>47</sup>. The reclaimed sand from our work had radium activity as low as  $0.207 \text{ Bq/g}$  ( $5.6$   
46  
47 527  $\text{pCi/g}$ ), with little risk for leaching of this radium; while the reclaimed clays (including salts and  
48  
49 528 organics) could be as high as  $3.7 \text{ Bq/g}$  ( $100 \text{ pCi/g}$ ). The activity of the eventually disposed  
50  
51 529 material ranged from  $0.74 \text{ Bq/g}$  to  $1.48 \text{ Bq/g}$  ( $20 \text{ pCi/g}$  to  $40 \text{ pCi/g}$ ). The disposed material will  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 530 thus contain lower net radium mass and lower volume, thereby reducing TENORM waste  
4  
5 531 disposal and landfill costs. Alternative treatment for solid waste management with elevated  
6  
7 532 radioactivity can be proposed following the findings from the TCLP and sequential extractions.  
8  
9  
10 533 Radium in the residual solids was associated with salts, carbonates, oxides, and possibly  
11  
12 534 surfactants at this study site.

13  
14  
15 535 *Limitations of this study*

16  
17 536 In this work, municipal tap water was used to make the slurries prior to experimental runs  
18  
19 537 on the HAC system. This protocol was an inherent artefact of conducting these pilot-scale tests at  
20  
21 538 Penn State, miles from the residual waste-processing facility. We acknowledge that such  
22  
23 539 intentional dilution would be impractical for a full-scale operation. Instead high-TDS produced  
24  
25 540 and flowback water would be present in any on-site slurries.

26  
27  
28 541 The fate of several heavy metals was not evaluated; however, non-heavy metal  
29  
30 542 concentrations of Fe, Al, and Mn in extraction fluids following the TCLP and sequential  
31  
32 543 extractions suggest that heavy metal concentration will be relatively low. Reported heavy metal  
33  
34 544 concentration in Marcellus Shale produced fluids are <1mg/L, compared to barium, calcium, and  
35  
36 545 magnesium at 50 – 30,000 mg/L<sup>25,84</sup>. The concentrations of these metals (Ba, Ca, and Mg) in the  
37  
38 546 extractants did not exceed 5 mg/L, therefore it is not expected that the heavy metals will have  
39  
40 547 significant concentrations. Additionally, we did not attempt to quantify the effect of treatment or  
41  
42 548 the leaching potential of these solids for other radionuclides such as Uranium (U). Eitrheim *et*  
43  
44 549 *al.*<sup>85</sup> found that U was mobile from Appalachian drilling wastes when the TCLP was applied. U  
45  
46 550 could also have been released by these solids given the sonication, cavitation, and oxidation  
47  
48 551 processes involved herein.  
49  
50  
51

## 552 **Conclusions and recommendations**

553 A novel process for recovering raw material from oil and gas residual waste was  
554 presented using hydroacoustic cavitation and advanced oxidants, combined with physical  
555 separation devices to create distinct streams of highly concentrated sand and clay. The separation  
556 of particles sizes affected radium distribution – the sand grains had low radium activities, as low  
557 as 0.185 – 0.74 Bq/g (5 – 20 pCi/g); whereas the clays (along with their associated salts and  
558 organics) had elevated radium activities, as high as 1.85 – 3.7 Bq/g (50 – 100 pCi/g). We  
559 propose that the sand grains can be reused as recycled hydraulic fracturing proppant. The  
560 separation of sand from clay and silt could reduce the volume of radium-containing wastes that  
561 are disposed in landfills, and also reduce the radium mass to landfills. This could represent a  
562 significant savings to facilities handling unconventional oil and gas waste. Additionally, the  
563 reclaimed sand could have market value in hydraulic fracturing drilling, or in other silica sand-  
564 using industries. Although the clays (and associated salts and organics) are currently of little  
565 market value, their elevated radium activity presents an opportunity to revise current waste  
566 handling practices for radioactive management. Disposing these radium-enriched salts and  
567 dislodged organic compounds downhole with hydraulic fracturing fluid will lower radium  
568 exposure and therefore risk to human health and the environment. Extractions performed on the  
569 residual waste indicated that in facilities that do not perform sulfate precipitation, radium is  
570 likely to be associated with dried salts and organic compounds.

571 The continued development of the Marcellus Shale and the underlying Utica Shale will  
572 result in greater use of raw materials and greater volume of solid and liquid waste. The Utica  
573 Shale is estimated to produce 2.5 times more produced water per unit gas than the Marcellus  
574 Shale<sup>86</sup>. These produced waters will contain NORM that could otherwise end up in

1  
2  
3 575 impoundment sludge or water treatment sludge. If not mitigated, the continued recycling of  
4  
5 576 produced water for hydraulic fracturing could cause an increase in TDS and radium activities <sup>48</sup>,  
6  
7  
8 577 potentially increasing the radioactivity and volume of sludge generated during treatment. This  
9  
10 578 work provides evidence that when these solids (sands, suspended solids, and sludge) are  
11  
12 579 collected in a waste handling facility, hydroacoustic cavitation with advanced oxidation followed  
13  
14 580 by physical separation devices can be applied to (a) reclaim the sands with lowered radioactivity;  
15  
16  
17 581 (b) separate the clays, salts and organics with high activity, and (c) reduce the potential of radium  
18  
19 582 leaching from the solids that require disposal.

**FIG. 1.** The Furness Newburge hydroacoustic cavitation circuit showing process flow and components (not to scale). Slurry from the *feed tank* was circulated through the cavitation box and hydroacoustic cavitation chamber for treatment. Following treatment, the slurry was pumped to the *hydroclone*: slurry came in through the inlet and two outflow streams were created: the underflow – with larger grains and higher solids concentration; and the overflow – with smaller grains and lower solids concentration. The hydrocyclone separated particles by size – fines were diverted to the overflow while coarser particles were diverted to the underflow. Next was the *spiral concentrator*: the underflow or overflow slurry was pumped upward from the sump to the top of the stack. Separation by gravity occurred as the slurry flowed downward through the spiral trough. The repulper at the end of the first stage (after 4 turns) rejected very coarse material into the central column (port 7). The remaining slurry passed over the final 4 turns and discharged through the spiral ports. The spiral separated particles primarily by density – low-density particles were diverted to ports 1 & 2, while high-density particles were diverted to ports 3-7. Red boxes denote sampling points. After <sup>62</sup> and <sup>70</sup>.

**FIG. 2.** Grain size analysis of HAC treatment (without AO – panels **A**, **B**, & **C**) and Control (No HAC – panels **D**, **E** & **F**) of solids collected at sampling points downstream of the treatment system. Fine particles will plot high and to the left, while coarse particles will plot low and to the right. Grain size analysis performed using US mesh sieves per ASTM D6913-04 from  $< 63 \mu\text{m}$  (#230 mesh i.e. clay) to  $>210 \mu\text{m}$  (#70 mesh i.e. sand). HAC causes disaggregation of homogenized solids when processing dewatered residual solids in 5% slurry with municipal tap water (for HAC treatment (panel **A**) compared to the No HAC Control (panel **D**)). Fine particles go to the overflow and large particles go to the underflow. Disaggregated solids can be further separated by the cyclone and spiral – with HAC, the process achieved higher concentration of clay (panel **B** vs **E**) and sand (panel **C** vs **F**). HAC treatment results in a distinct particle size distribution.

**FIG. 3.** Optical light microscopy (Zeiss Axiophot microscope) provided visual assessment of the “As received” sand grains aggregated with clays and fines on their surfaces (left panel), compared to the HAC treatment (right panel), which was effective at disaggregating the clay fines off the sand. Further physical separation devices resulted in reclaimed sand that was free of clays and silts.

**FIG. 4.** Radium-226 activities on the size-classified solids from various sample ports: initial and post TCLP extraction. Radium-226 activities (Bq) have been normalized to initial mass (g) of the solid prior to extraction. Error bars denote combined standard error in radium measurements and mass measurements. Samples were taken from the feed, hydrocyclone, underflow (under), and overflow (over). Red boxes highlight HAC-AO treatment. Size classification using US mesh sieves per ASTM D6913-04:  $< 63 \mu\text{m}$  is clay (#230 mesh),  $>210 \mu\text{m}$  is sand (#70 mesh), and in-between is silt. Radium leached significantly from the “As Received” clay sized solids. These results indicated that treatment diminished the risk of radium leaching out in the landfill.

**FIG. 5.** Major metal mobility of the size-classified samples following TCLP extraction, in mg metal extracted per initial g of solids. Samples were taken from the feed, hydrocyclone, underflow (under), and overflow (over). Radium mobility strongly followed barium mobility. Leaching did not result in concentrations above regulatory limits for TCLP and landfill disposal.

**FIG. 6.** Radium-226 activities of the sequentially extracted, size-classified, treated solids. Radium-226 activities (Bq) have been normalized to initial mass (g) of the solid prior to extraction. Error bars denote combined standard error in radium measurements and mass measurements. Step 0 (■): Initial solid; Step 1 (■): DI water rinse for soluble salts; Step 2 (■): 1 M ammonium acetate for surface sites; Step 3 (■): 9% acetic acid for carbonates; Step 4 (■): 0.1 M hydrochloric acid for oxides. ■ shading for sand, ■ for silt, and ■ for clay. The “As received” samples are demarcated with a lighter shade.

**FIG. 7.** Major metal mobility of the size-classified, sequentially extracted samples in mg metal extracted per g of solids prior to each extraction step. Step 1 (■): DI water rinse for soluble salts; Step 2 (■): 1M ammonium acetate for surface sites; Step 3 (■): 9% acetic acid for carbonates; Step 4 (■): 0.1 M hydrochloric acid for oxides. ■ shading for sand, ■ for silt, and ■ for clay. The “As received” samples are demarcated with a lighter shade.

**FIG. 8.** Mass lost from the size-classified solids following sequential extractions. Step 1 (■): DI water rinse for soluble salts; Step 2 (■): 1M ammonium acetate for surface sites; Step 3 (■): 9% acetic acid for carbonates; Step 4 (■): 0.1 M hydrochloric acid for oxides; and Recalcitrant mass (■) following steps 1-4. ■ shading for sand, ■ for silt, and ■ for clay. The “As received” samples are demarcated with a lighter shade.

**Table 1.** A four step sequential extraction was designed to investigate radium associations in the HAC-treated residual waste. After <sup>73</sup> and <sup>74</sup>. Extractions performed with 20:1 fluid-to-solid ratio. After extraction, solids were separated by centrifugation, rinsed with DI water, and dried. Radium-226 activities of the dried solids were determined by gamma spectroscopy.

<i>Step</i>	<i>Description</i>	<i>Extraction Targets</i>	<i>Target Examples</i>
0	Oven dried "As Recvd" and wet sieved, size-classified solids (includes TDS)	No extraction	All soluble and insoluble solids
1	Distilled-deionized (DI) Water for 24 hours	Soluble salts/evaporated pore water	NaCl, BaCl <sub>2</sub> , CaCl <sub>2</sub> , & SrCl <sub>2</sub>
2	1M Ammonium Acetate for 12 hours	Surface exchangeable/ low-charge interlayer	From surface of sand and silt grains; from illite clay interlayer
3	9% Acetic Acid for 12 hours	Carbonate minerals	CaCO <sub>3</sub> , MgCO <sub>3</sub> , Al <sub>2</sub> (CO <sub>3</sub> ) <sub>3</sub> & Fe <sub>2</sub> (CO <sub>3</sub> ) <sub>3</sub>
4	0.1 M Hydrochloric Acid for 12 hours	High-charge interlayer/partial silicate/oxides	MnO <sub>x</sub> , FeO <sub>x</sub>

**Table 2.** Summary of the mass-balance normalized raw material recovery for control (No HAC) and treatment (HAC). Up to 15% of the residual solid waste can be reclaimed as clays and 38% as sand.

<i>Sampling point</i>	<i>No HAC</i>		<i>HAC</i>	
	<i>Clay</i>	<i>Sand</i>	<i>Clay</i>	<i>Sand</i>
Feed	24%	35%	47%	23%
Overflow	8%	1%	11%	0%
Spiral Port 1	<b>8%</b>	1%	<b>10%</b>	0%
Spiral Port 2	<b>2%</b>	0%	<b>5%</b>	0%
Underflow	36%	7%	20%	14%
Spiral Port 3	5%	<b>1%</b>	2%	<b>3%</b>
Spiral Port 7	6%	<b>2%</b>	3%	<b>35%</b>

The percentage represents how much of the material sampled was clay (< 63  $\mu\text{m}$  i.e. #230 mesh), or sand (>210  $\mu\text{m}$  i.e. #70 mesh), relative to the starting mass of the “As Received” material.

**Table 3.** Summary of the raw material recovery and market opportunity from HAC-treated residual waste assuming a disposal volume of 5,000 tons/y.

	<i>Recovery</i>	<i>Price of pristine material</i>	<i>Estimated benefit assuming 5,000 tons/y of residual solid</i>
Silica Sand	~37%	\$84/ton <sup>35</sup>	Resell at \$30/ton = \$50,000 - \$60,000/y
Resin coated/Ceramic proppant	~37%*	\$200 - \$500/ton <sup>79</sup>	Resell at \$70 - \$150/ton = \$130,000 - \$280,000/y
Wasted Material	~63%	<b>-\$76/ton<sup>80</sup></b>	Potential cost savings of \$140,000/y

\* Assuming similar recovery of resin coated sand or ceramic proppant as for silica sand.

By applying a novel system to unconventional oil and gas residual waste, we were able to recover valuable raw materials, which could represent significant savings to disposal cost, while aiding radioactivity management.
