## A localized molecular automaton for *in situ* visualization of proteins with specific chemical modifications†

Lu Liu, Siqiao Li, Anwen Mao, Guyu Wang, Yiran Liu, Huangxian Ju  and Lin Ding \*

Given the powerful regulation roles of chemical modification networks in protein structures and functions, it is of vital importance to acquire the spatiotemporal chemical modification pattern information in a protein-specific fashion, which is by far a highly challenging task. Herein, we design a localized DNA automaton, equipped with an *anticoding-coding* sequential propagation algorithm, for *in situ* visualization of a given protein subtype with two chemical modifications of interest on the cell surface. The automaton is composed of three probes respectively for the protein and two types of modifications. Once anchored on the cell surface and triggered, the automaton performs sequential protein-localized, DNA hybridization-based computations on the proximity status of each modification type with the protein and contracts the set of close proximity information into a single fluorescence signal turn-on using the designed algorithm. The modular and scalable features of the automaton enable its operation in scaled-down versions for protein-specific identification of one given modification. Thus, this work opens up the possibility of using automata for revealing complex regulation mechanisms of protein posttranslational modifications.

### Introduction

Chemical modification of proteins is a major means which nature uses to diversify the structure up to functionality of proteins, which involves the covalent attachment of different chemical groups, such as phosphate, carbohydrate, acetyl groups *etc.*, to amino acid residues of proteins.<sup>1,2</sup> These modifications play important roles in the regulation of protein properties and activities and govern their dynamic and intricate interactions in biological processes.<sup>3–5</sup> More importantly, proteins can be multiply modified with different groups at different residues or at the same residue either competitively or sequentially, creating a continuous regulatory network.<sup>6</sup> Owing to the rapid development of MS-based proteomic techniques, hundreds of modifications have been identified.<sup>7,8</sup> However, the revelation of the individual functions of these modifications and the effects of their mutual interactions on a given protein are largely hampered by the lack of protein-specific imaging techniques, particularly those capable of acquiring the *in situ* spatiotemporal distribution information of a specific protein subtype carrying a certain set of chemical modifications.<sup>9</sup>

To meet the challenge, one needs to respectively label the target protein and modifications of interest (MOIs) with probes and design physical or (bio)chemical interactions to report the close proximity of each probe pair (one on the protein and the other on a MOI). On this basis, the key obstacle is how to link these protein-localized interactions in isolation into an information propagation pathway, which will terminate by a signal switch to indicate the existence of a particular protein subtype with a given modification pattern on the cell surface. In this context, DNA nanodevices, which can operate sophisticated computation at the molecular level in a complex biological environment,<sup>10–14</sup> offer a robust, elegant and versatile tool, owing to the predictable hybridization and programmable assembly of DNA. For example, several innovative cell discrimination platforms have been developed by combining DNA strand displacement cascade with antibody<sup>11</sup>- or aptamer<sup>12</sup>-based recognition for the evaluation of cell surface markers. However, DNA nanodevices designed for *in situ* computation of chemical modification patterns of a given protein on the cell surface are still missing.

Herein, we have developed a localized DNA automaton capable of *in situ* translation of a particular protein subtype with dual MOIs on the cell surface into a fluorescence output signal, which relies on performing protein-confined computation according to a designed *anticoding-coding* sequential propagation algorithm (Fig. 1). For proof-of-concept demonstration, we chose a cancer-associated transmembrane glycoprotein, epithelial cell adhesion molecule (EpcAM), as the model

Fig. 1 Principle of the localized molecular automaton computing on protein modifications, using EpCAM as the model. (A) Scheme showing the *anticoding-coding* sequential propagation algorithm and the corresponding DNA reactions. (B) Schematic illustration of the assembly of the three probes onto the corresponding protein characteristics. (C) Scheme of the automaton executing on the cell surface EpCAM and outputting a final fluorescence signal.

protein, which can serve as a diagnostic and prognostic marker and an immunotherapeutic target,<sup>15,16</sup> and introduced two types of model MOIs into cells: (1) incorporating homopropargylglycine (HPG) into proteins to yield alkyne modification,<sup>17,18</sup> (2) displacing termini sialic acids (Sia) of protein-carried glycan chains with azide Sia.<sup>19,20</sup> The first one represents direct chemical modification of amino acid residues of the protein backbone, while the second one illustrates an important and common protein posttranslational modification (PTM) type, *i.e.* glycosylation.<sup>4</sup> Sia was chosen as the model glycan due to the fact that sialylation is one of most widely occurring cancer-associated changes in glycosylation<sup>4</sup> and might add a new dimension to direct therapeutic interventions.<sup>21</sup> Thus the protein identity (C<sub>P</sub>), HPG installation (C<sub>H</sub>), and azide Sia (C<sub>S</sub>) are the three illustrative “protein characteristics (PCs)” subjected to computation by the automaton.

The automaton contains three probes respectively for C<sub>H</sub>, C<sub>P</sub>, and C<sub>S</sub> (Fig. 1B), which are designed in a modular manner. Each probe is composed of (1) a reaction/recognition motif (azide (N<sub>3</sub>) for C<sub>H</sub>, an EpCAM-specific aptamer sequence SYL3C (Apt) for C<sub>P</sub>,<sup>22</sup> and dibenzocyclooctyne (DBCO) for C<sub>S</sub>) as the anchoring module for specifically directing probe assembly onto PCs and (2) an *anticoding-coding* oligonucleotide part (partially complementary DNA duplex H'·H and P'·P for C<sub>H</sub> and C<sub>P</sub>, respectively, and hairpin S'·S for C<sub>S</sub>) as the computation module for collecting identity and proximity information of

PCs. The DNA sequences without the prime symbol (H, P, and S) are *coding* oligonucleotides and linked with the corresponding anchoring motifs. They carry the “identity information” of PCs during the computation. Those marked with the prime symbol (H', P', and S') are *anticoding* ones, which originally “mask” the *coding* partners, and can later be triggered by hybridization with the upstream *coding* sequences to release their masked *coding* partners. This action propagates “identity information” between *coding* parts of probes located in close spatial proximity in the order C<sub>H</sub> → C<sub>P</sub> → C<sub>S</sub> (Fig. 1A). Only when the three types of probes are co-localized within the region of a single protein, *i.e.* the EpCAM carries C<sub>H</sub> and C<sub>S</sub> simultaneously, can the automaton complete the calculation and output a final fluorescence signal on the cell surface (Fig. 1C). Note that C<sub>P</sub> is set as the connecting link for checking its proximity status with C<sub>H</sub> or C<sub>S</sub> due to (1) scalability consideration: the program can be simply scaled down by curtailing the first or third step for identification of the specific protein with one MOI; (2) efficiency consideration: C<sub>H</sub> → C<sub>P</sub> and then C<sub>P</sub> → C<sub>S</sub> information propagation can benefit from accelerated DNA reaction and catalytic signal generation, respectively (*vide infra*).

The detailed *anticoding-coding* sequential propagation algorithm is as follows: after anchoring the probes onto the corresponding PCs, a time coding strand T is added to initiate the program. The algorithm performs a three-step sequential YES logic-gate computation, through two steps of toehold-mediated strand displacement reactions<sup>23,24</sup> and one step of restriction endonuclease nicking reaction,<sup>25</sup> according to a “if YES then proceed” rule on individual proteins on the cell surface (Fig. 1A): T binds to the exposed toehold sequence of *anticoding* H', thus exposing the entire length of the *coding* H (eqn (S1) in Fig. S1A†). The released H can bind to the toehold of *anticoding* P' and displace *coding* P (eqn (S2) in Fig. S1B†), indicating the close proximity of C<sub>H</sub> and C<sub>P</sub>. Then the liberated P binds to the fluorescence-quenched *anticoding-coding* hairpin S'·S (with a quencher and fluorophore modified at S' and S, respectively), yielding a nicking site for nicking endonuclease (NE, Nt.BbvCI).<sup>26</sup> The cleavage enables not only fluorescence recovery due to the separation of the fluorophore from the quencher, but also the re-liberation and thus reuse of P (eqn (S3) in Fig. S2†). The latter achieves the cyclic cleavage of S'·S, thus yielding a downstream catalytic signal propagation mode, which enables the assessment of the protein (or protein subtype)-specific C<sub>S</sub> level. The finally obtained single signal turn-on indicates the close proximity of C<sub>H</sub> and C<sub>S</sub> with C<sub>P</sub>.

## Results and discussion

We first designed a whole set of *anticoding* and *coding* sequences (Table S1†) and demonstrated the working principles for each individual DNA reaction step *in vitro* by native polyacrylamide gel electrophoresis (PAGE) and fluorescence analysis (Fig. S1–S3†). To exclude possible interference of the Apt sequence in DNA reactions, P-Apt was used instead of P for *in vitro* experiments. Then we went on to check the feasibility of the cascades of sequential two or three step reactions. For the cascade reaction composed of two steps of strand displacement (eqn (1) in

Fig. 2 *In vitro* demonstration of the feasibility of DNA reactions exploited by the automaton. (A) The two-step cascade reaction composed of two strand displacement reactions. Native PAGE and fluorescence analysis of a system containing T (900 nM), H'·H (450/300 nM), and P'·P·Apt (150/100 nM, P'·Q·F·P·Apt is used for fluorescence detection). The 518 nm peak FI of P'·Q·F·P·Apt is set to 1. (B) The two-step cascade reaction composed of the second strand displacement reaction and NE-assisted cyclic nicking reaction. Native PAGE analysis of a system of H (300 nM), P'·P·Apt (150/100 nM), S'·S (1 μM), and NE (1000 U mL<sup>-1</sup>). The concentrations for fluorescence analysis are one tenth those for PAGE. The 518 nm peak FI of Q·S'·S·F is set to 1. (C) The 3-step holo cascade reaction. Concentrations for native PAGE are the same as those used in (A) and (B). T (90 nM), H'·H (45/30 nM), P'·P·Apt (15/10 nM), Q·S'·S·F (100 nM), and NE (100 U mL<sup>-1</sup>) are used for fluorescence analysis. The 518 nm peak FI of Q·S'·S·F is set to 1.

Fig. 2A), only when T and H'·H were both added to P'·P·Apt could new bands for H, T·H', H·P', and P·Apt be generated, indicating the occurrence of a sequential two-step strand displacement reaction (Fig. 2A, left). In the absence of T, H' and P' exhibited excellent masking capabilities toward their

respective partners (lane 2). The significant enhancement of fluorescence intensity (FI) at 518 nm of P'·Q·F·P·Apt (9-fold) upon incubation with both T and H'·H and the background-level signals of P'·Q·F·P·Apt alone or in the presence of either T or H'·H further provided proof for the cascade strand displacement and efficient masking of H (or P·Apt) by H' (or P') (Fig. 2A, right).

The feasibility of cascading the second strand displacement with the cyclic nicking cleavage reaction (eqn (2) in Fig. 2B) was evaluated likewise (Fig. 2B and S4A†). The addition of both H and P'·P·Apt to S'·S (Q·S'·S·F, for fluorescence analysis) and NE resulted in the disappearance of the S'·S band, the appearance of new bands for P·Apt, H·P' and the cleavage product, and a 13-fold enhancement of FI (Fig. 2B), demonstrating successful connection of the two reactions. The indispensable role of H in boosting this cascade reaction and the efficient masking of P·Apt (or S) by P' (or S') were also confirmed (Fig. 2B and S4†). Note that the complete depletion of S'·S was achieved at a 0.1 : 1 molar ratio of P·Apt and S'·S (lane 4, Fig. 2B, left), demonstrating the recycling usage of P·Apt for S'·S cleavage (also demonstrated in Fig. S2†). Considering that there are usually abundant glycans linked to a single protein, this P recycling usage feature endows the automaton with the capability to reflect the sialylation extent of the target protein (or protein subtype).

For the holo three-step cascade reaction (eqn (3) in Fig. 2C), as expected, only when T, H'·H, P'·P·Apt, S'·S (or Q·S'·S·F, for fluorescence analysis), and NE were mixed together, can the cleavage of S'·S (or Q·S'·S·F) be observed (Fig. 2C and S4B†). Taken together, these *in vitro* experiments verified the feasibility of all the DNA reactions along the *anticoding-coding* signal propagation axis. Moreover, the possibilities of undesired hybridization were eliminated exquisitely, owing to the efficient masking capability of the *anticoding* strands toward their *coding* partners. This ensures that during probe anchoring processes, the *coding* strands will not be liberated to yield or propagate false positive signals, which is the prerequisite to using the algorithm for *in situ* automaton execution.

The successful implementation of the automaton on the cell surface relies on the specific probe assembly on the corresponding PCs. The model protein with dual MOIs was constructed by co-adding Ac<sub>4</sub>ManNAz and HPG to the culture medium during the MCF-7 cell culturing process. Considering that HPG acts as the replacement of methionine (Met) to be incorporated into proteins,<sup>17,18</sup> a Met-free culture medium is used here. Probes are assembled onto the cell surface PCs in the following order (Fig. S5†): P'·P·Apt binding to C<sub>P</sub> via Apt recognition, Q·S'·S·F-DBCO linking to C<sub>S</sub> via the copper-free click reaction, and H'·H-N<sub>3</sub> conjugating to C<sub>H</sub> via Cu(I)-catalysed azide-alkyne cycloaddition.<sup>18,27</sup> Each type of probe docking was respectively examined by confocal laser scanning microscopy (CLSM) observation of individual binding signals using appropriately modified probes in two set of experiments: (1) only one type of probe was assembled and (2) the complete set of probes was assembled. In the first group of experiments, as expected, for each type of PC, the corresponding counterpart probes displayed bright fluorescence on the cell surface, while

in the absence of either moiety of the click reaction/recognition pair, an indiscernible binding signal could be observed (Fig. S6–S10†). These results verified the successful incorporation of the two MOIs into cells and the specificities of probe docking. Additionally, the maintaining of the duplex structure of  $P' \cdot P\text{-Apt}$  and  $H' \cdot H\text{-N}_3$  during the assembly process was confirmed (Fig. S11†) and the installation of HPG onto EpCAM was also validated by immunoprecipitating azide-PEG<sub>3</sub>-biotin treated cell lysate, followed by western blotting analysis with anti-biotin antibody (Fig. S12†). The incubation time for Ac<sub>4</sub>ManNAz and HPG with MCF-7 cells was optimized to be 48 h (Fig. S8 and S10†), which was used for cellular incorporation of the two MOIs unless otherwise stated. In the second experimental group, when performing complete PC labeling using  $P' \cdot P\text{-Apt}$ ,  $Q\text{-S}'\text{-S-F-DBCO}$  and  $H' \cdot H\text{-N}_3$ , only negligible background signal was observed (Fig. S13†), demonstrating the stability of  $Q\text{-S}'\text{-S-F-DBCO}$  in real cell experimental settings. On this basis, using appropriately modified probes, each type of PC was respectively lighted up (Fig. S13†) and also, the three types of PCs were simultaneously lighted up (Fig. S14†), confirming the successful assembly of probes and exclusion of the cross interference among the labeling processes.

With probes anchored in place, the automaton can be executed *in situ* to visualize protein subtypes with specific chemical modification patterns. The modular nature of the automaton and the connecting position of C<sub>P</sub> between C<sub>H</sub> and C<sub>S</sub> enable us to use the first or last two computation steps for identification of the protein subtype with one MOI. The first scaled-down version (automaton I, Fig. 3A) involves the anchoring of  $H' \cdot H\text{-N}_3$  and  $P' \cdot Q\text{-F-P-Apt}$  on the cell

surface and executes according to eqn (1) by computing on two questions: “START?”, followed by “Is C<sub>P</sub> with C<sub>H</sub>?”. Indeed, using C<sub>H</sub>-installed MCF-7 cells as the model, the addition of T led to an obvious fluorescence signal of liberated  $F\text{-P-Apt}$  on the cell membrane (Fig. 3B), indicating the existence of EpCAM with HPG installed. However, without T addition (particularly, the toehold region of T) or  $H' \cdot H\text{-N}_3$  binding, only very weak background fluorescence could be observed, suggesting that the automaton completed the computation just as prescribed (Fig. 3B and S15A†). A time-resolved visualization of C<sub>H</sub>-installed EpCAM on the cell surface was performed and a greater output signal was observed along with longer HPG incubation time with cells (Fig. S16†). The enhancement of the output might be attributed to higher expression of newly synthesized, HPG-installed EpCAM and higher effective HPG concentration on individual proteins, and the latter could accelerate the strand displacement rate.<sup>28</sup>

The other scaled-down version (automaton II) just covers the last two steps and computes based on eqn (2), which requires the assembly of  $P' \cdot P\text{-Apt}$  and  $Q\text{-S}'\text{-S-F-DBCO}$  on the C<sub>S</sub>-installed cell surface, and uses *coding H* as the time coding strand. Upon being triggered, this automaton analyses “START” and then “Is C<sub>P</sub> with C<sub>S</sub>?”. Specifically, after H displaces  $P\text{-Apt}$ , the released  $P\text{-Apt}$  exhibits protein-localized hybridization with  $Q\text{-S}'\text{-S-F-DBCO}$  in a cyclic fashion assisted by NE nicking, thus propagating the identity information of C<sub>P</sub> to multiple C<sub>S</sub> in close proximity (Fig. 3C). Analogously, automaton II successfully completed computation by displaying bright fluorescence on the cell surface, illuminating

Fig. 3 *In situ* visualization of EpCAM with one MOI using automaton I or II. (A) Scheme of automaton I for *in situ* visualization of HPG-installed EpCAM on the cell surface. (B) CLSM imaging of MCF-7 cells after incorporation of HPG and further treatment with different probe sets. (C) Scheme of automaton II for *in situ* visualization of EpCAM-carried C<sub>S</sub> on the cell surface. (D) CLSM imaging of MCF-7 cells after incorporation of Ac<sub>4</sub>ManNAz and further treatment with different probe/NE sets. Scale bars: 20 μm.

the  $C_S$  only carried by EpCAM (Fig. 3D and S15B†). The output FI was 2.3 times that for automaton I, which could be attributed to the signal propagation from single  $C_P$  to multiple  $C_S$ , thus reflecting the sialylation level of EpCAM. The dynamic EpCAM-specific  $C_S$  incorporation was monitored using automaton II (Fig. S17A†), and a gradual increase of output FI was observed with longer  $Ac_4ManNAz$  incubation time (Fig. S17B†). This result demonstrated that the proposed automaton could be used for protein-specific monitoring of the dynamic incorporation of MOIs.

The docking of automaton I and II generates the holo automaton (*i.e.* automaton III), which enables the identification of EpCAM with dual MOIs based on eqn (3) using the complete set of probes (Fig. 4). On the basis of the two questions just the same as those for automaton I, the third question is “Is  $C_P$  with both  $C_H$  and  $C_S$ ?” (Fig. 1A). Similarly, the recycled use of **P-Apt** enabled the output to represent the expression level of  $C_S$  on a given protein subtype, *i.e.* HPG-installed EpCAM. The binding stability of **P'·P-Apt** was evidenced by executing a counterpart automaton using **P'·Q·F-P-Apt** and **S'-S-DBCO** to replace **P'·P-Apt** and **Q-S'-S-F-DBCO**. The fluorescence recovery of the probe **P'·Q·F-P-Apt** after the addition of **T** and **NE** was observed, which was due to the hybridization between **H** and **P'·Q** (Fig. S18†).

The imaging specificity of automaton III was scrutinized from both protein and MOI aspects. For protein specificity, negligible output could be observed with the omission of **P'·P-Apt** (Fig. 4), suggesting the dependence of output generation on **Apt** recognition. In further support, EpCAM expression was downregulated by siRNA, as confirmed by both western blotting analysis (Fig. S19A†) and **F-P-Apt** binding (Fig. S19B and C†), which led to an obvious reduction of output (Fig. 5A and E), thus verifying that the output indeed came from EpCAM rather than other proteins. To exclude the possibility of DNA hybridization between probes anchored on different proteins, either **H'·H** or **Q-S'-S-F** was guided to anchor at an adjacent protein, using a large-sized and highly expressed glycoprotein mucin 1 (MUC1) as the model, while the other two probes in both cases were assembled just as before. As expected, only negligible signals

Fig. 4 *In situ* visualization of EpCAM with dual MOIs using automaton III. CLSM imaging of MCF-7 cells after incorporation of  $Ac_4ManNAz$  and HPG and further treatment with different probe/NE sets. Scale bar: 20  $\mu$ m.

Fig. 5 (A) Demonstration of the protein specificity of automaton III by transfecting cells with either siRNA or siRNA-NC (control siRNA). Control: no transfection. (B) Demonstration of the dependence on HPG installation for automaton III execution using MCF-7 cells treated with Met (instead of HPG) and  $Ac_4ManNAz$ . Control: no displacement. (C) Demonstration of the Sia imaging specificity of automaton III by NEU cleavage. Control: no NEU treatment. (D) Monitoring the variation of Sia on HPG-installed EpCAM in response to TM or BAG treatment using automaton III. Control: no treatment. (E–H) FI obtained from (A)–(D), respectively. Data are statistically analyzed by Student's *t*-test (\*\* $p < 0.001$ ; NS: not significant). Scale bars: 20  $\mu$ m.

could be observed upon executing the two counterpart automatons (Fig. S20†). The dependence on HPG (or **H'·H-N<sub>3</sub>**) for executing automaton III was confirmed from the indiscernible signal obtained when displacing HPG with Met for treating cells (Fig. 5B and F) or executing automaton III in the absence of **H'·H-N<sub>3</sub>** (Fig. 4). Finally, the  $C_S$  detection specificity was verified from the significant decrease of output when using  $\alpha$ 2-3,6,8,9 neuraminidase A (NEU) to cleave terminal Sia on the outer cell surface (Fig. 5C and G).<sup>29</sup>

Next, the feasibility of automaton III for quantification of the target protein was evaluated systematically. Executing the automaton on dual-labeled cells after being treated with NEU of different concentrations revealed a linear relationship between FI from CLSM images and the NEU concentration, thus demonstrating the capability of relative quantification of the azide Sia level of the HPG-installed EpCAM (Fig. S21†). Similarly, the feasibility of quantification of EpCAM containing dual MOIs was also examined on cell samples treated with siRNA with different concentrations. The linear FI decrease with increasing siRNA concentration verified that the output of the automaton could reflect the expression level of the target protein subtype with two MOIs quantitatively (Fig. S22†).

The ability of automaton III to identify specific proteins carrying dual MOIs with  $C_S$  as the terminal computation target

can be used for monitoring the glycan expression variation of a specific protein subtype during disturbed glycan biosynthesis processes. The extracellular domain of EpCAM is *N*-glycosylated only;<sup>30</sup> thus the inhibition of *N*-glycosylation, rather than *O*-glycosylation pathways, may influence the glycoforms of EpCAM. Consistent with this, a remarkable decrease of output was obtained when treating MCF-7 cells with an *N*-glycosylation inhibitor, tunicamycin (TM),<sup>31</sup> and negligible change could be observed after benzyl- $\alpha$ -GalNAc (BAG, an *O*-glycosylation inhibitor) treatment (Fig. 5D and H).<sup>32</sup> Considering that the EpCAM expression and HPG installation levels in MCF-7 cells showed little change during drug treatment (Fig. S23 and S24<sup>†</sup>), the observed output decrease upon TM treatment indicated a reduced sialylation level in HPG-installed EpCAM. The indiscernible change upon BAG treatment also verified the sugar specificity of automaton III, as *O*-glycans carried by adjacent proteins could not contribute to the output.

To demonstrate the modular and generically adaptable design of the automaton for other proteins containing natural PTMs, an automaton (automaton IV) that can illustrate the phosphorylation of an HPG-incorporated epidermal growth factor receptor (EGFR) upon epidermal growth factor stimulation is designed using HeLa cells as the model. In this context, the three probes are **H'·H-N<sub>3</sub>**, **P'·P-Apt<sub>E</sub>**, and **Q-S'·S-F-Ab**, respectively, for C<sub>H</sub>, EGFR, and phosphotyrosine. Upon the addition of **T**, obvious fluorescence could be observed inside HeLa cells (Fig. S25<sup>†</sup>), indicating the existence of phosphorylated and HPG-labeled EGFRs.

## Conclusions

In conclusion, unlike prior studies mainly focusing on computing cell identity by performing DNA reactions at the global cell membrane,<sup>11–13</sup> we have built a localized molecular automaton capable of *in situ* assessment of the chemical modification characteristics of the target protein on the cell surface. The automaton has harnessed different types of exquisite DNA nanotechnology to choreograph the *anticoding-coding* sequential propagation algorithm, achieving the visualization of a protein subtype with dual MOIs. The automaton is modular and scalable, which enables the operation of scaled-down versions for protein-specific identification of one MOI as desired. The automata have also been used for MOI tracking in a protein-specific and further protein subtype-specific manner. The automata can be readily expanded to more complex algorithms by simply inserting other probe layers to reflect the hierarchical structure of biomacromolecules. Thus this work opens up the possibility of using automata for *in situ* visualization and tracking of protein PTMs and also paves the way for revelation of the sophisticated mechanisms of the PTM network (including PTM crosstalk) for regulation of protein functions.
