Encapsulation of crystalline and amorphous Sb_2S_3 within carbon and boron nitride nanotubes†

Griffin M. Milligan,^a Dmitri Leo Mesoza Cordova,^a Ze-Fan Yao,^b Brian Y. Zhi,^a Lyndsey R. Scammell,^c Toshihiro Aoki^d and Maxx Arguilla^{*a}

The recent rediscovery of 1D and quasi-1D (q-1D) van der Waals (vdW) crystals has laid foundation for the realization of emergent electronic, optical, and quantum-confined physical phenomena in both bulk and at the nanoscale. Of these, the highly anisotropic q-1D vdW crystal structure and the visible-light optical/optoelectronic properties of antimony trisulfide (Sb_2S_3) have led to its widespread consideration as a promising building block for photovoltaic and non-volatile phase change devices. However, while these applications will greatly benefit from well-defined and sub-nanometer-thick q-1D structures, little has been known about feasible synthetic routes that can access single covalent chains of Sb_2S_3 . In this work, we explore how encapsulation in single or multi-walled carbon nanotubes (SWCNTs or MWCNTs) and visible-range transparent boron nitride nanotubes (BNNTs) influences the growth and phase of Sb_2S_3 nanostructures. We demonstrate that nanotubes with smaller diameters had a more pronounced effect in the crystallographic growth direction and orientation of Sb_2S_3 nanostructures, promoting the crystallization of the guest structures along the long-axis [010]-direction. As such, we were able to reliably access well-ordered few to single covalent chains of Sb_2S_3 when synthesized within defect-free SWCNTs with sub-2 nm inner diameters. Intriguingly, we found that the degree of crystalline order of Sb_2S_3 nanostructures was strongly influenced by the presence of defects and discontinuities along the Sb_2S_3 -nanotube interface. We show that amorphous nanowire domains of Sb_2S_3 form around defect sites in larger, multi-walled nanotubes that manifest inner wall defects and discontinuities, suggesting a means to manipulate the crystallization dynamics of confined sub-10 nm-thick Sb_2S_3 nanostructures within nanotubes. Lastly, we show that ultranarrow amorphous Sb_2S_3 can impart functionality onto isolable BNNTs with photocurrent generation in the pA range which, alongside the dispersibility of the Sb_2S_3 @BNNTs, could be leveraged to easily fabricate photoresistors only a few nm in width. Altogether, our results serve to solidify the understanding of how q-1D vdW pnictogen chalcogenides crystallize within confined synthetic platforms and are a step towards realizing functional materials from ensembles of encapsulated heterostructures.

1 Introduction

Recent years have seen a drastic uptick in the synthesis and characterization of atomically precise low-dimensional crystals

that approach the single-atom-thick regime. Such studies have led to the discovery and rediscovery of many useful two-dimensional (2D),^{1–3} one-dimensional (1D), and quasi-one-dimensional (q-1D) van der Waals (vdW)^{4,5} materials with

nascent physical properties. The anisotropy inherent in the structure of these materials has enabled the development of facile top-down exfoliation^{6–9} or bottom-up growth^{10–13} methods to achieve sub-10 nm nanocrystals with tunable morphologies such as nanosheets, nanoribbons, and nanowires, and shape- or dimension-dependent properties. This structural and chemical tunability has led to discoveries including the transition from indirect band gap in the bulk to direct band gap in monolayer MoS₂ (ref. 14) and the quantum spin Hall effect in graphene in 2D.¹⁵ Morphological tunability in 1D, on the other hand, has led to discoveries including an enhanced intrinsic photovoltaic effect in TaS₃,¹⁶ high coercivity in CrSbSe₃,¹⁷ high breakdown current in TaSe₃,¹⁸ high-fidelity transport in (TaSe₄)₂I,¹⁹ and the approach of an indirect-to-direct band gap crossover in ultrathin Sb₂S₃ nanowires.¹³ The latter material, antimony trisulfide, has been at the forefront of q-1D vdW materials research not only as a model structural phase but also due to its unique optoelectronic and structural properties arising from its anisotropic q-1D structure and visible-light optical properties. This earth abundant material is found in nature as the mineral stibnite^{20,21} and as the amorphous mineraloid metastibnite.²² In more recent times, it has gained significant interest as a potential thin film photovoltaic material with a tunable band gap between 1.6–2.85 eV,^{23–27} high predicted power conversion efficiency in tandem cells,^{28,29} and a high absorption coefficient ($\alpha > 10^4 \text{ cm}^{-1}$).³⁰ Moreover, it has been demonstrated that Sb₂S₃ is also a phase change material (PCM),^{25,31} as the crystalline (c-Sb₂S₃) and amorphous (a-Sb₂S₃) phases that can be interconverted thermally or optically, with broad ranging implications for use in optical switching, tunable emitters/absorbers, and, in particular, non-volatile data storage.^{32,33} This class includes other pnictogen- and tetrrel-based chalcogenide materials often based on antimony and/or germanium, including Sb₂Se₃,³¹ Ge₂Sb₂Te₅,³⁴ Ge₂₀Sb₂₀S₂₀Se₂₀Te₂₀,³⁵ Ge₁₅Sb₄₀S₁₅Se₁₅Te₁₅,³⁶ and many others.

From a structural standpoint, Sb₂S₃ is a q-1D vdW material comprised of sub-nanometer-thick ribbons of [Sb₄S₆]_n that infinitely extend in one direction along the crystallographic *b*-axis ([010]-direction) and are held together along the other two axes (basal plane) by weak vdW forces.²⁰ Yet, these forces are not equal along various crystallographic axes. The terminal trivalent Sb atoms along the [Sb₄S₆]_n chain (in contrast to the pentavalent core Sb atoms) express stereochemically active lone pairs which interact with the electronegative S atoms terminating the neighboring ribbon. This results in a binding interaction along the *c*-axis ([001]-direction) that is approximately double that of the interaction along *a*-axis ([100]-direction).³⁷ The stereochemical activity of this lone pair has been found to stem from the Sb 5s orbital mixing with S 3p orbitals to express bonding anisotropy in the anti-bonding state. Beyond its implications to the optical and electronic properties of Sb₂S₃, it was also demonstrated that these anisotropic bonding motifs can be leveraged to control the nanoscale morphology of Sb₂S₃ nanocrystals. Top-down approaches like mechanical and solvent exfoliation of a bulk stibnite crystal are known to cleave the crystal predominantly along the weakest *a*-axis direction and result in 2D nanosheets and ribbons,^{38,39} rather than 1D

nanowires as one might expect from the underlying q-1D lattice. To some extent, the differing electronic interactions can also be leveraged in bottom-up growth to direct the crystallization of Sb₂S₃ nanostructures by tuning the precursor concentration and temperature with vapor phase growth, allowing access to a variety of morphologies such as nanowires, nanoribbons, and nanosheets from the same [Sb₄S₆]_n chain building blocks but with differing optical properties and electronic structures.¹³ Additionally, in single covalent chains of Sb₂S₃, computational predictions of a rare indirect-to-direct gap transition in 1D and q-1D vdW semiconductors, in addition to a tightly bound excitonic state, have been demonstrated.⁴⁰ Experimentally, nanowires display an emission distinct from bulk Sb₂S₃ at and below 100 nm in diameter.¹³ Despite the tremendous efforts towards growing nanoscale structures of Sb₂S₃,^{41–43} a reliable methodology enabling the isolation of single covalent chains of crystalline Sb₂S₃ by any existing top-down or bottom-up approach—and one that is not obscured by the anisotropic inter-chain interactions arising from stereochemically-active lone pairs—has remained elusive.

Encouragingly, an effective method that directly influences the diameter of nanowire growth down to sub-nanometer thickness is *via* nanotube encapsulation.^{44,45} In this method, pre-grown nanotubes with open ends are used as nanoscale reaction vessels, into which materials of interest migrate *via* capillary action in melt or vapor phase.⁴⁵ For the purpose of our report, these materials are denoted as material@NT. In the spectrum of well-defined nanotube encapsulants, carbon nanotubes (CNTs) are the best understood, with many fundamental studies offering insight into the structure of confined and metastable materials. For example, many optically-active semiconducting materials have been encapsulated in ultra-narrow carbon nanotubes, including single NbSe₃ chains,⁴⁶ narrow direct gap IV–VI materials like SnSe,⁴⁷ SnTe,⁴⁸ and PbTe,⁴⁹ and more recently lead halide perovskites.^{50,51} Still, despite these efforts, material@CNT heterostructures are generally limited to structural observations due to the metallic/low band gap^{52,53} and high absorbance^{54,55} of the nanotube meaning conductivity and optical signal of the host material is completely occluded by the CNT. Alternatively, the visible-range transparent and electrically insulating nature^{56–59} of boron nitride nanotubes (BNNTs)⁶⁰ facilitates the straightforward measurement of optoelectronic properties in material@BNNT heterostructures.⁶¹ These heterostructures are less studied and are, so far, limited to molecular filling with organic dyes^{62,63} or nanoparticle/rod filling^{61,64–69} apart from few studies which involved Te@BNNT,⁷⁰ NbSe₃@BNNT,⁴⁶ and KX@BNNT (X = Cl, Br, I)⁷¹ which are the only extended structures encapsulated within BNNTs to the best of our knowledge. Leveraging the properties of BNNTs is essential to translate the potential of nanotube encapsulation to the fundamental understanding of optical properties of encapsulated materials and to realize practical application in electronic and photonic devices. More generally, the utility of diverse nanotubes in terms of structure (carbon *versus* boron nitride) and sizes (various diameters and number of walls) could provide a means to further understand how the immediate chemical and structural environment

within nanotubes (*e.g.* defects) play a role in the structure and phase of guest materials in materials@NTs.

In this report, we detail the encapsulation of Sb_2S_3 within nanotubes of various diameters and chemical compositions with the goal of understanding the limit of structural confinement of Sb_2S_3 when encapsulated within NTs and how the resulting size, structure, and degree of crystallinity influence the properties of the resulting Sb_2S_3 @NTs. In smooth, defect-free single walled CNTs (SWCNTs), we obtained few to single covalent chains of $\text{c-Sb}_2\text{S}_3$ with a high filling efficiency. Yet, using other nanotube sources, we found that the degree of crystallinity of the Sb_2S_3 is heavily dependent on the surface roughness of the nanotube it interfaces with, evidenced by high resolution transmission electron microscopy (HRTEM) and complemented by Raman spectroscopy. This is most pronounced in BNNTs, where we primarily observed $\text{a-Sb}_2\text{S}_3$ filling around nanotube defects (pinches, kinks, BN aggregates) with crystal formation only appearing where the nanotubes were especially smooth. Likewise, we demonstrate that this is also the case in MWCNTs with larger diameters which also contained defects within the inner surface. We generally observed that the amorphization is driven by the surface smoothness rather than the host-guest chemistry between Sb_2S_3 and the BNNT or MWCNT. Moreover, we found that the amorphization/defect ratio is dependent on the nanotube diameter, suggesting that it is driven by the interfacial stability of the amorphous phase compared to the crystalline Sb_2S_3 phase. Finally, we observe emergent optical properties of $\text{a-Sb}_2\text{S}_3$ @BNNT, including a visible range absorption at 502 nm/2.47 eV consistent with the optical signatures of $\text{a-Sb}_2\text{S}_3$ thin films and a pronounced photocurrent response demonstrating that BNNTs can be sensitized by the guest $\text{a-Sb}_2\text{S}_3$ phase.

2 Results and discussion

We achieved the encapsulation of Sb_2S_3 in single walled carbon nanotubes (SWCNTs) *via* a mixed melt growth process using SWCNTs with opened ends (annealed in air 420 °C 5 hours) and a large excess of pre-synthesized, phase-pure, Sb_2S_3 powder (Fig. S1†) heated above its melting point at 600 °C. In a mixed-melt growth of this type, it is generally considered that capillary action drives liquid Sb_2S_3 melt into the nanotubes. As the reaction ampoule cools, the encapsulated Sb_2S_3 crystallizes within the nanotubes.⁴⁵ Once synthesized, we used high-resolution transmission electron microscopy (HRTEM) and scanning transmission electron microscopy (STEM) to evaluate the success and resulting quality of the nanotube filling. By our direct observations in HRTEM, we could readily access Sb_2S_3 @SWCNT at a high filling efficiency as all SWCNTs that we found were filled with the guest phase (Fig. 1A). As expected of the q-1D vdW structure of Sb_2S_3 , the covalent axis was determined to align parallel to the long axis of the nanotube, with a measured d spacing of 1.9 Å which corresponds to the [020]-direction of the native Sb_2S_3 structure $d_{(020)} = 1.918$ Å (Fig. 1A and C). This indicates that Sb_2S_3 has a propensity to crystallize along the long-chain covalent axis direction strongly influenced by the direction of the confined 1D nanotube. The consistency

of the d -spacing with the native structure also indicates that minimal distortion was caused by the confinement. Energy dispersive X-ray spectroscopy (EDS) mapping performed with 80 kV annular dark-field (ADF) STEM also confirmed the identity of the phase, with an apparent ratio of 2:3 Sb/S within the SWCNTs (Fig. 1B). As we saw previously with our work on Sb_2Se_3 ,⁷² this method of confinement within SWCNTs accessed ultrathin nanowires of Sb_2S_3 within nanotubes of fewer than 2 nm, meaning that only 1–2 covalent chains with 1.04 nm distance between terminal sulfur atoms could occupy a given nanotube.

We performed Raman spectroscopy to further verify that minimal structural modulation had occurred as was observed by HRTEM imaging (Fig. 1D). Firstly, Raman signals from both $\text{c-Sb}_2\text{S}_3$ and empty SWCNTs are in close agreement with literature values.^{24,73} Sb_2S_3 contained five well-resolved peaks: 193 cm^{-1} , 246 cm^{-1} , 280 cm^{-1} , 302 cm^{-1} , and 309 cm^{-1} , with the two A_g signals occurring at 280 and 309 cm^{-1} being the most prominent. In the region that we surveyed, the SWCNTs contained only radial breathing mode (RBM) signals.^{74–76} The most intense radial breathing mode also occurred at the highest wavenumber, 181 cm^{-1} , before the signals abruptly ceased at the higher wavenumber region of the spectra. Raman spectroscopy revealed minute, though obvious, differences between the filled and empty SWCNTs. A broad feature centered around 266 cm^{-1} that is well above the highest radial breathing mode intensity emerged with a shoulder intensity around 310 cm^{-1} . We assign this broad feature to the two A_g modes of Sb_2S_3 that are broadened significantly and red-shifted from confinement effects. The highest SWCNT RBM peak, however, remained centered at approximately 180 cm^{-1} . This is in contrast with our work on Sb_2Se_3 @SWCNT, where the observable A_g mode of Sb_2Se_3 did not shift and is indicative of a more pronounced confinement effect or nanotube-guest interaction. We note that, while the red-shifted A_g mode is low intensity and broad which makes it highly susceptible to background noise, this observed peak difference ($\Delta = 14$ cm^{-1}) is far too considerable to attribute to noise alone. The well-resolved Raman peaks also enabled us to evaluate the SWCNT graphitic signals. From these, we found little-to-no difference in the G^- -band or G^+ -band, which is suggestive that the SWCNT itself was not distorted significantly (Fig. S4†).

As with other nanotube-encapsulated crystalline phases, the successful encapsulation of single covalent chains of Sb_2S_3 within SWCNTs prompted us to investigate the evolution of the optical properties of bulk Sb_2S_3 compared to Sb_2S_3 @SWCNT. To this end, we obtained the Kubelka–Munk absorbance spectrum ($F(R_\infty)$) from the diffuse reflectance spectrum (DRS) of the Sb_2S_3 @SWCNT and compared it with bulk Sb_2S_3 and empty SWCNTs (Fig. 1E). As expected, SWCNTs displayed broadband absorbance while bulk Sb_2S_3 showed a characteristic absorbance band edge at 790 nm/1.57 eV, which is close to literature values.²³ We, however, did not observe any apparent difference between empty and filled SWCNTs in the region we surveyed, with only broadband CNT absorbance visible. This contrasts with our work on Sb_2Se_3 @SWCNT, where we saw the onset of a distinct edge in the heterostructure not present in empty

SWCNTs⁷² and is likely due to the lower absorption coefficient of Sb_2S_3 compared to Sb_2Se_3 .³¹ From these measurements, it became clear that the observation of confined optical properties of Sb_2S_3 down to the single chain regime in encapsulated heterostructures requires a transparent nanotube as a host material.

We then turned to insulating boron nitride nanotubes (BNNTs) to confine Sb_2S_3 in an optically transparent and electrically insulating nanotube host. We acquired BNNTs with pre-opened ends and employed an identical mixed-melt growth method to synthesize confined Sb_2S_3 covalent chains within BNNTs. It is unlikely that the general mechanism of encapsulation is different between CNTs and BNNTs, and we suspect that the heterostructure formation is still capillary action-driven for this system. Upon synthesis, we then performed HRTEM to determine the filling success and degree of crystallinity of the resulting Sb_2S_3 @BNNT structures (Fig. 2). We observed that the BNNTs ranged in size, with an average diameter of about 2.9 nm and a standard deviation of 0.9 nm ($n = 71$). Several of the nanotubes surveyed fell outside one standard deviation, meaning that, at the minimum, a single covalent Sb_2S_3 chain could be isolated within the BNNTs used in this study (Fig. 2A). When crystalline, *c*- Sb_2S_3 grew within the BNNT heterostructures identically to the SWCNTs, with the [020]-direction of

the covalent chains found to be oriented parallel to the long-axis of the BNNT and matched the 1.9 Å *d*-spacing of the (020) Miller planes of Sb_2S_3 (Fig. 2A and B).²⁰ Once again, similar to the SWCNTs, the crystallization was strongly influenced by the confined and 1D nature of the BNNTs. We also found that some nanotubes hosting single covalent chains did not contain enough periodic motifs in the micrograph to perform a fast Fourier transform (FFT), although the real space images are measurable and displayed 0.38 interatomic distances consistent with the lattice spacing of the (010) Miller planes in Sb_2S_3 (Fig. 2A).

Intriguingly, most of the nanotubes surveyed contained amorphous material that was encapsulated within (Fig. 2B and C). We stress that great care was taken to ensure that this was not caused by electron beam damage upon exposure during the imaging. We, in fact, observed that areas which were crystalline did not decompose under the beam for several seconds under the same imaging conditions. We also note that amorphous aggregates appeared where the nanotube host harbored defects in the innermost tube wall or at any point the nanotube walls were not parallel (Fig. 2C). Generally, we found that the following features of the nanotubes were observed to cause defective sites: nanotube walls could slope inward towards one another (Fig. 2C(I)), nanotube walls could be jagged (Fig. 2C(II)),

or the nanotube could be pinched inward at one point (Fig. 2C(III)). We also observed that a gradual curve, as long as the nanotube walls remained parallel, would not result in this amorphous behavior (Fig. 2C(I)). From these surveys and observations, we reason that defects in the nanotube walls may be causing this unique behavior that we did not observe in any of the highly pristine SWCNTs. We do not entirely discount other scenarios that could cause the guest Sb_2S_3 phase to form amorphous domains. For example, the encapsulation of an off-stoichiometric phase of Sb_xS_y during the mixed-melt process could result in the failed crystallization of Sb_2S_3 . We, however, only observed a close to stoichiometric 2:3 Sb/S ratio in amorphous regions using STEM-EDS (Fig. 2D). To probe the possible influence of the surface chemistry of the nanotubes (BNNT *versus* CNT), understanding whether the formation of the amorphous phase was a result of a defective interface or was strictly a result of the chemical identity of the nanotube wall would require the demonstration of a similar defect-induced amorphization of Sb_2S_3 within carbon nanotubes.

We demonstrate that the defect-induced amorphization of Sb_2S_3 is nanotube-agnostic using a source of relatively large diameter multi-walled CNTs (MWCNTs; ~ 10 nm inner diameter) which contained defects and structural imperfections

along the nanotube walls. For these experiments, we oxidized the MWCNTs in open air (ambient) for 10 hours at 420 °C to ensure that the majority of the CNT walls were opened before filling with Sb_2S_3 (Fig. 3). Using HRTEM imaging, we observed both the c- Sb_2S_3 and a- Sb_2S_3 filling of the MWCNTs with the former as the more dominant filling phase (Fig. 3A and B). These results are corroborated by the Raman spectroscopy of the Sb_2S_3 @MWCNT samples which displayed two distinct peaks centered squarely at the A_g modes of Sb_2S_3 (Fig. S6[†]) rather than a single broad feature consistent with literature on amorphous Sb_2S_3 .³¹ Unlike both of the previously discussed samples (Sb_2S_3 @SWCNT and Sb_2S_3 @BNNT), Sb_2S_3 @MWCNT did not exclusively form Sb_2S_3 nanostructures that possess [010] covalent axes that ran perfectly parallel to the long-chain axis of the MWCNT (Fig. 3A). This was a likely result of the additional free volume that is afforded by the larger MWCNT host. This crystallization behavior also appeared to be diameter dependent: nanotubes with larger diameters such as the 13.5 nm-diameter nanotube crystallized Sb_2S_3 nanostructures that possessed $[\text{Sb}_4\text{S}_6]_n$ chains which had covalent axes oriented off from the MWCNT nanotube long-axis; while nanotubes with narrower diameters like in the case of the 7.1 nm-diameter MWCNT sample crystallized with the covalent axes only

Fig. 3 Sb_2S_3 encapsulated within MWCNTs. (A) Representative HRTEM of crystalline Sb_2S_3 @MWCNTs. The topmost image contains a model (left), simulated image (middle), and real image (right). For all three images, the corresponding FFT of the micrographs are located on the top-right panel. (B) Representative HRTEM of amorphous $\text{a-Sb}_2\text{S}_3$ @MWCNTs. The crystalline domains of $\text{c-Sb}_2\text{S}_3$ are highlighted in red for easier visualization, while the $\text{a-Sb}_2\text{S}_3$ domains are highlighted in blue. (C) EDS map of a $\text{c-Sb}_2\text{S}_3$ nanowire bundle encapsulated within a MWCNT. (D) EDS map of an amorphous $\text{a-Sb}_2\text{S}_3$ nanowire within a MWCNT.

slightly tilted from MWCNT nanotube long-axis. Just as we observed with Sb_2S_3 @BNNTs, smooth, defect-free regions of MWCNT with well-ordered nanotube walls resulted in the formation of crystalline $\text{c-Sb}_2\text{S}_3$ guest phase, while regions around defect sites contained $\text{a-Sb}_2\text{S}_3$ (Fig. 3B). In the topmost image of Fig. 3B, we also found individual $\text{c-Sb}_2\text{S}_3$ covalent chains that are spatially localized with the amorphous $\text{a-Sb}_2\text{S}_3$ phase in close proximity.

To further understand this unusual but reproducible behavior we once again closely examined the possibility that the amorphization is a product of an off-stoichiometric phase with the larger region of interest provided by our MWCNT source (Fig. 3C and D). In a heterostructure where we observe distinct lattice fringes along the length of the wire *via* HRTEM imaging signifying crystalline order, a corresponding EDS map revealed both Sb and S were present at 35 and 65 atomic percent, respectively, which is close to the stoichiometric ratio of Sb_2S_3 . We attribute the small 5% discrepancy from the true 2 : 3 Sb/S ratio to instrumental error. While there could have been residual sulfur present on the TEM grid or coating the wires, the EDS map of the S K intensity is exclusively localized to the inner diameter of the nanotubes. Likewise, we also observed a ratio of 36 : 64 Sb/S for an amorphous phase within the nanotube that we mapped subsequently (on the same grid) which, due to the close agreement of the discrepancy attributable to the measurement error, we are confident the stoichiometric ratio of Sb/S is not the cause of the amorphization of Sb_2S_3 @NTs. This observation further supports the notion that amorphous formation of Sb_2S_3 within nanotubes is a direct result of the physical effect of the defect on the Sb_2S_3 rather than the specific chemistry of the host nanotube. We note that nanotubes with large inner diameters retain crystallinity despite the presence of

defects (Fig. 3A), signifying that this effect, too, has a nanotube diameter dependence and is likely suppressed by the available free volume for crystallization in larger nanotubes.

Contrastingly, we also observed many Sb_2S_3 nanowires that were amorphous within the BNNTs despite an apparently smooth nanotube wall making up a majority of the Sb_2S_3 @BNNT sample and sought to understand the rationale for this crystallization behavior (Fig. 4). More specifically, the heterostructures in question appeared to have no noticeable defects or discontinuities along the nanotube walls and showed little to no curvature (Fig. 4A). These nanotubes, for consistency, had diameters that are close to the previously discussed nanotubes. Through these samples, we examined how the more pronounced formation of amorphous domains could be influenced, to some extent, by the difference in interfacial chemistry between CNTs and BNNTs. Electron donation may occur between the CNT and the guest Sb_2S_3 , which may be critical to the stabilization of crystalline $\text{c-Sb}_2\text{S}_3$. DFT analysis of a single Sb_2S_3 chain projected two-unit-cells long in a (21,0) SWCNT and (21,0) single-walled BNNT (SWBNNT) revealed a significant difference in the host-to-guest electron donation depending on the chemical identity of the nanotube (Fig. 4C). Bader analyses of these simulated structures showed that 0.435 electrons were transferred from the SWCNT to the two-unit-cell-long Sb_2S_3 in Sb_2S_3 @SWCNT_(21,0) while the behavior was reversed and insignificant for the BNNT, with a nominal value of 0.046 electrons transferred from the two-unit-cell-long long Sb_2S_3 to the BNNT in Sb_2S_3 @SWBNNT_(21,0).

These results are further corroborated by X-ray photoelectron spectroscopy (XPS) of our experimental $\text{a-Sb}_2\text{S}_3$ @BNNT and $\text{c-Sb}_2\text{S}_3$ @SWCNT samples (Fig. S10 and Table S2[†]). As observed from our DFT calculations, the dominant electron

Fig. 4 HRTEM of $\text{Sb}_2\text{S}_3@\text{BNNTs}$ and DFT simulations of $\text{Sb}_2\text{S}_3@\text{nanotubes}$. (A) Representative HRTEM image of amorphous $a\text{-Sb}_2\text{S}_3$ domains within apparently smooth and well-defined BNNTs. (B) Representative HRTEM images of BNNTs before filling with Sb_2S_3 . Highlighted in arrows are the BN aggregates that are encapsulated inside the nanotubes. (C) DFT and electron density difference map of crystalline Sb_2S_3 in a (21,0) SWCNT and (21,0) SBWNT.

localization occurs on S rather than Sb in $\text{Sb}_2\text{S}_3@\text{SWCNT}$. When we compare the values of the S 2p peaks between $c\text{-Sb}_2\text{S}_3@\text{SWCNT}$ ($2p_{3/2} = 161.67$ eV, $2p_{1/2} = 162.92$ eV, and $\Delta = 1.25$ eV) and $a\text{-Sb}_2\text{S}_3@\text{BNNT}$ ($2p_{3/2} = 161.95$ eV, $2p_{1/2} = 163.20$ eV, and $\Delta = 1.25$ eV) the carbon nanotube has a 0.28 eV lower value, indicating a greater degree of electron density. Meanwhile, the Sb 3d peak values between $c\text{-Sb}_2\text{S}_3@\text{SWCNT}$ ($3d_{5/2} = 529.95$ eV, $3d_{3/2} = 539.31$ eV, and $\Delta = 9.36$ eV) and $a\text{-Sb}_2\text{S}_3@\text{BNNT}$ ($3d_{5/2} = 529.97$ eV, $3d_{3/2} = 539.4$ eV, and $\Delta = 9.43$ eV) are much closer in value and consistent with other Sb_2S_3 nanowire reports.¹³ Both @SWCNT and @BNNT Sb and S values are above those of the experimentally determined bulk Sb_2S_3 values (Sb $3d_{5/2} = 529.72$ eV, $3d_{3/2} = 539.08$ eV, and $\Delta = 9.36$ eV; S $2p_{3/2} = 161.57$ eV, $2p_{1/2} = 162.81$ eV, and $\Delta = 1.24$ eV). While both heterostructures are vdW in nature, this electron reorganization in $\text{Sb}_2\text{S}_3@\text{SWCNT}$ likely creates a dipole that stabilizes the interaction between guest and host facilitated by carbon's conductivity, while the $\text{Sb}_2\text{S}_3@\text{SBWNT}$ system more closely resembles a true vdW interaction. This donation and subsequent weak dipole interaction also has an interesting impact on the thermal stability of the material by thermogravimetric analysis (TGA) (Fig. S11†). While both @NT structures decompose at lower temperatures than the bulk material (632.1 °C) as expected of nanomaterials,⁷⁷ the $c\text{-Sb}_2\text{S}_3@\text{SWCNT}$ material (536.6 °C) appears to have a much greater degree of thermal

stability compared to the $a\text{-Sb}_2\text{S}_3@\text{BNNT}$ material (246.9 °C). The fact that the encapsulated Sb_2S_3 in BNNT is predominantly amorphous could also contribute to this lower thermal stability. Still, despite the appreciable difference in the extent of electron transfer between the readily donating CNT and the relatively inert BNNT, both simulated structures yielded energetically favorable and comparable interactions based on the calculated binding energies (E_B) with a resulting $E_B = -1.83$ eV in $\text{Sb}_2\text{S}_3@\text{SWCNT}$ and $E_B = -1.52$ eV in $\text{Sb}_2\text{S}_3@\text{BNNT}$. While the $\text{Sb}_2\text{S}_3@\text{SWCNT}$ shows a slightly more negative E_B and a more energetically favorable interaction, the $\text{Sb}_2\text{S}_3@\text{BNNT}$ is still energetically favorable, and we find clear examples of $c\text{-Sb}_2\text{S}_3$ nanowires within the BNNTs. From an experimental standpoint, Sb_2S_3 nanowires can also readily crystallize outside of a nanotube which means that ultrathin Sb_2S_3 is not a metastable phase.¹³ As such, based on these arguments, we posit that as electron donation from the carbon nanotubes stabilizes the Sb_2S_3 chain, the lack of donation from BNNTs does not destabilize the chain.

To complement these observations, we also experimentally evaluated the quality of the empty BNNT precursors that we used for filling and found obvious aggregates of BN already inside most of the tubes (Fig. 4B). These aggregates, along with other inner tube wall defects and discontinuities, are present at the time of nanotube synthesis and were not removed unlike

other BN impurities. From our imaging studies, we found that the aggregates persisted after calcining the BNNTs at 800 °C in open air for 5 hours and even after washing in *aqua regia* for 5 h followed by calcination (Fig. S12†). Observations from other literature reports that utilized the same nanotube source also observed the same aggregates encapsulated within the nanotubes resulting from the aggressive post-synthesis treatment to open the ends.⁷⁸ These observations suggest that these aggregates likely act in the same way nanotube wall defects do, disrupting crystal packing and causing the amorphous phase to be preferred. In line with our prior discussion, we further reason that this is the likely cause for the formation of amorphous domains for the large majority of the Sb₂S₃ within the BNNTs despite the BNNT walls being predominantly smooth, rather than the lack of electron donation from the host nanotube to the guest Sb₂S₃ structure.

From HRTEM imaging coupled with EDS mapping, we have corroborated that the degree of crystallinity found in Sb₂S₃@-NTs is strongly dependent on the crystalline order and quality of material it interfaces with. In smooth and continuous nanotubes, we consistently observed c-Sb₂S₃. In contrast, in jagged or narrowing nanotubes, we found a-Sb₂S₃ domains especially at narrow (<10 nm) nanotube diameters. We surmise that this difference can be rationalized in terms of the interfacial stability between the Sb₂S₃ phase and the host nanotube. As a unique 1D PCM, the literature has established that the energy difference between the c-Sb₂S₃ and a-Sb₂S₃ phases is low.⁷⁹ Owing to its crystalline and highly anisotropic nature, the growth of c-Sb₂S₃ has the geometric propensity to adopt a 1D nanostructure as imposed by its [Sb₄S₆]_n chain building blocks. Against an atomically rough or discontinuous nanotube surface, however, a propagating chain and bundle of c-Sb₂S₃ will require more free space within the nanotube (and along the direction of the chain propagation) to consistently crystallize linearly as 1D crystals and will be limited by the distance of the furthest extended defect of the nanotube wall. Hence, while the c-Sb₂S₃ may be slightly more energetically favorable than the amorphous phase outside the nanotube, the presence of defects along the nanotube inner walls could destabilize the favorable interfacial vdW interaction between the encapsulated Sb₂S₃ phase and the nanotube host. In contrast, a-Sb₂S₃ can readily solidify to occupy any geometric configuration and shape of the host nanotube. This structural modularity of an amorphous phase means it can readily fill the irregular void space that would destabilize the c-Sb₂S₃ phase, thereby maximizing the surface stability of the a-Sb₂S₃@NT heterointerface.

We note that the amorphous phase is not limited to the areas immediately surrounding the defect and, instead, appears to saturate a sizable nanotube region several nanometers beyond the nanotube defect (Fig. 2C and 3B). From these results, we posit that thermodynamic surface stability of the amorphous phase at the interface drives the immediate surrounding nanotube area to favor the formation of amorphous domains, diminishing the crystalline phase except in very smooth regions where the c-Sb₂S₃ phase preferentially forms. Our observation of the diameter dependence of this effect, wherein defects do not strictly cause amorphous phases or domains at large diameters

(>10 nm), suggests a competition between Ostwald ripening⁸⁰ and the recently discovered defect-mediated ripening.⁸¹ The former involves a large crystalline domain within the nanotube that drives the system toward a crystalline phase regardless of defects while the latter involves the higher intrinsic interfacial stability of an amorphous phase within the nanotube that drives the system towards that the formation of amorphous domains at the vicinity of defect sites along the nanotube walls. In terms of growth, this would imply that the liquid Sb₂S₃ melt migrates into the nanotubes at high temperatures. Then, as the reaction cools, the Sb₂S₃ melt solidifies in a way that minimizes its surface energy: either by directionally crystallizing in small, defect-free nanotubes in the direction parallel to the long axis of the nanotube or by condensing as an amorphous solid to occupy the defective regions. At larger nanotube diameters, we observe that both mechanisms break down, resulting in decreased directionality in the crystallization and crystalline quality regardless of defects as the stability of a “bulk” crystal becomes more pronounced than that of the interface. We do not see any significant difference between CNTs and BNNTs in this regard, as even though CNTs have a more stable interface with c-Sb₂S₃ based on our calculations, we still find a-Sb₂S₃ at CNT wall defects. Structural selectivity has been reported previously, in which nanotube diameter dictates the phase of the guest,^{82,83} though amorphous phases at defects and diameter-dependent control over covalent direction have not. We note that this result is not unique to 1D systems but is also consistent with literature reports in comparable 2D synthetic platforms, in which the formation of thin film domains of a-Sb₂S₃ templated onto a graphene substrate is greatly facilitated by ozone-induced defects in the surface.²⁵

Our understanding of the formation of a-Sb₂S₃ and c-Sb₂S₃ domains in BNNTs has provided an opportunity to evaluate the optoelectronic properties of confined amorphous domains of Sb₂S₃ encapsulated within an optically transparent (in the visible range) and electrically insulating BNNTs. These Sb₂S₃@BNNT heterostructures are predominantly comprised of a-Sb₂S₃@BNNTs with some c-Sb₂S₃@BNNTs (Fig. 5). From the sample under study, the consequences of encapsulation were immediately obvious from the red-orange appearance (in contrast with the empty BNNTs that are white) of the a-Sb₂S₃@BNNT ensemble collected from the mixed melt synthesis product (Fig. 5A). In our efforts to quantify the absorbance of the a-Sb₂S₃@BNNT, we found that estimating the Kubelka-Munk absorbance from DRS was inconsistent, as empty BNNTs reflected more of the incident light than the KBr used for the sample matrix and the blank measurement. Instead, we used UV-vis spectroscopy to probe the absorption signatures of a-Sb₂S₃@BNNTs suspended in isopropanol (Fig. 5B). The resulting spectrum showed an obvious absorption edge that emerged at ~502 nm/2.47 eV. This is in the high energy end of the typical 1.7–2.8 eV absorption range of a-Sb₂S₃ as found in the literature^{25,27,30} and is a significant 0.89 eV blue shift from the 790 nm/1.57 eV band gap absorption edge of bulk crystalline Sb₂S₃. Meanwhile, the Raman spectrum of a-Sb₂S₃@BNNT matches literature reports of a-Sb₂S₃,³¹ with only one broad peak centered around 300 cm⁻¹. This broad peak corresponding to

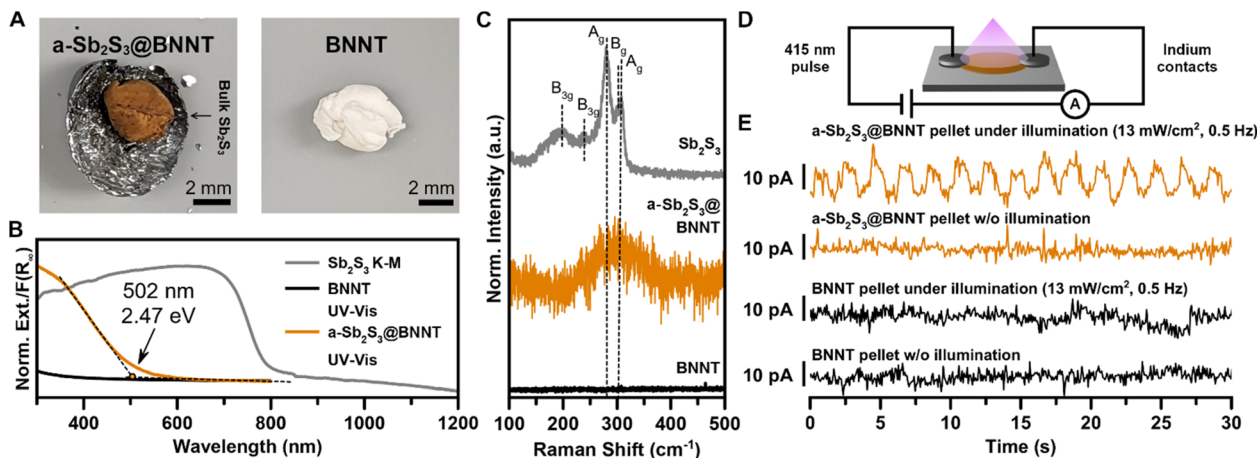

Fig. 5 Optoelectronic properties of primarily a-Sb₂S₃ encapsulated within BNNTs. (A) Optical images of a-Sb₂S₃@BNNTs (left) and BNNTs (right). (B) UV-vis spectra of a-Sb₂S₃@BNNTs and BNNTs overlaid with DRS of crystalline Sb₂S₃. (C) Raman spectra of a-Sb₂S₃@BNNTs, crystalline Sb₂S₃, and BNNTs. (D) Device schematic of pressed pellet of a-Sb₂S₃@BNNTs. (E) Photocurrent response of pressed pellet of purified a-Sb₂S₃@BNNTs illuminated with a 13 mW cm⁻² light source.

the amorphous phase does not display a shoulder peak unlike the Raman peak apparent in our c-Sb₂S₃@CNTs, corroborating our observations made by HRTEM that most of the material is a-Sb₂S₃ within the BNNTs (Fig. 5C). While amorphous, these results still demonstrate that BNNTs can be sensitized using an inorganic guest (amorphous or crystalline) to absorb well within the visible range.

Finally, we demonstrate that filling BNNTs with mostly a-Sb₂S₃ also imparts a degree of electrical conductivity to the heterostructure when pressed as ensemble pellets (Fig. 5D and E). To fabricate devices from filled and empty BNNTs, we pelletized each at 14 MPa then fabricated roughly uniform rectangular sections from the resulting pellet. Comparative measurements for both filled and empty BNNTs were made using identical contacts (indium metal) and device geometry (two-probe contacts), with dimensions that were measured and accounted for. The devices were then illuminated by a pulsed 415 nm LED light at 13 mW (Fig. 5D). From the current vs. time plot, we observed a well-resolved and prominent photocurrent response for the a-Sb₂S₃@BNNT device but not for the empty BNNT device (Fig. 5E). This indicates any measurable photocurrent arises from the a-Sb₂S₃ nanostructures encapsulated inside of the nanotubes. We also observed an uptick in conductivity, from 5.1 nS cm⁻¹ in empty BNNTs to 8.3 nS cm⁻¹ in a-Sb₂S₃@BNNTs (Fig. S13†). These results suggest that pronounced alterations in the optical, electrical, and optoelectronic behavior of composite BNNT-encapsulated 1D or quasi-1D vdW crystals can be realized even with amorphous encapsulated domains. From these results, we envision that the dispersibility of the Sb₂S₃@BNNT assembly and the stability of the ultranarrow heterostructures indicates that significant improvements can be made *via* more optimized device fabrication to improve the active building blocks and create effective single wire photoresistors of only a few nm in width. The insulating nature of the BNNT means the conduction is strongly influenced by the Sb₂S₃ guest which could potentially serve as

ultranarrow semiconductor building blocks for next-generation transistor platforms.⁷⁰ Finally, BN-semiconductor heterostructures have demonstrated good capability as thermoelectric devices in 2D,⁸⁴ and this class of heterostructure could also serve as a 1D platform for waste heat recovery and thermoelectric power generation.

3 Conclusion

In this report, we demonstrated that single- and multi-walled carbon and boron nitride nanotube encapsulation can be used to control the size, growth direction/orientation, and degree of crystallinity of Sb₂S₃, a model quasi-1D vdW crystal, from nanowire bundles down to the single chain regime. We establish that using highly uniform SWCNTs facilitates the formation of continuous few-chain nanowires and single covalent chains, directing growth strictly to the [010]-direction. On the contrary, we systematically observed that using either BNNTs or MWCNTs with inner wall defects led to the formation of a-Sb₂S₃ domains localized around the defects. We observed that this effect was nanotube size-/diameter-dependent, with larger nanotubes crystallizing encapsulated Sb₂S₃ nanostructures regardless of defects in the tube wall in addition to diminished control over the growth orientation. Beyond our understanding of the possible growth and crystallization pathways of Sb₂S₃, our ability to synthesize ensembles of Sb₂S₃@nanotube heterostructures with a visible light-transparent and insulating BNNT also enabled us to evaluate the unobscured optical and electrical properties of ultrathin, predominantly amorphous, Sb₂S₃ few-chain nanowire bundles. Altogether, our study on the synthetic modulation of Sb₂S₃ nanostructures, either crystalline or amorphous and at or approaching the single chain regime, underscores the critical role of the host-guest interface on the formation of well-defined structural domains, the spectrum of accessible optical and electronic states, and the prospects of encapsulated quasi-1D vdW guest

nanomaterials with applications in energy conversion such as photovoltaics and thermoelectric generation as well as in computing and data storage devices.
