Abstract: Metal halide perovskites have arisen as a new family of semiconductors for radiation detectors due to their high stopping power, large and balanced electron-hole mobility-lifetime ($\mu\tau$) product, and tunable bandgap. Here, we report a simple and low-cost solution processing approach using additive-assisted inverse temperature crystallization (ITC) to grow cesium lead bromide (CsPbBr₃) single crystals with low-defect density. Crystals grown from precursor solutions without additives tend to grow fastest along the [002] direction, resulting in crystals shaped as small elongated bars. The addition of choline bromide (CB) proves to mediate the crystallization process to produce large single crystals with a cuboid shape, allowing for more practical fabrication of gamma-ray detectors. This new additive-assisted growth method also improves the resulting crystal quality to yield a reduction in the density of trap states by over one order of magnitude, relative to a crystal grown without CB. The detector fabricated from a CB-assisted solution-grown perovskite CsPbBr₃ single crystal is able to acquire an energy spectrum from a cesium-137 (¹³⁷Cs) source with a resolution of 5.5% at 662 keV.

Keywords: CsPbBr₃, Perovskite single crystal, Gamma-ray detector, Inverse temperature crystallization solution method, Energy spectrum

Introduction

Nuclear radiation detectors are capturing growing attention due to the broad potential application in materials science, physics research, nuclear energy, medical imaging, and radiation safety¹⁻⁴. Gamma-ray spectroscopy, which is able to resolve the energy of the incoming gamma-ray and identify the radioactive species and isotopes, is a critical sector in the radiation detection market. Germanium (Ge) is one of the most developed semiconductors which has been successfully employed in gamma-ray spectroscopy for over 40 years⁵. High purity Ge (HPGe) detectors have evolved with resolution better than 0.4%^{6, 7}. However, to achieve such high performance, the small bandgap of HPGe detectors (0.7 eV) requires to be cooled to below 120 K in order to suppress the overwhelming leakage current associated with the thermal excitation of intrinsic charge carriers. In contrast, compound semiconductors, with the advantages of a broad range of stopping power and adjustable wide bandgaps, have been developed as more attractive options for room temperature detection. Mercuric iodide (HgI₂), cadmium telluride (CdTe), cadmium zinc telluride (CdZnTe), Gallium Arsenide (GaAs), Lead Iodide (PbI₂)⁸⁻¹¹ are common compound semiconductors for gamma-ray detection. Due to its good electron transport properties ($10^{-3} \sim 10^{-2} \text{ cm}^2 \text{ V}^{-1}$ mobility-lifetime product¹²), a high band gap (1.5~1.6 eV) and high resistivity ($\geq 10^{10} \Omega \text{ cm}$), CdZnTe has been the primary focus for research and commercialization as room temperature detectors. However, it is difficult to achieve low-cost, high-quality CdZnTe single crystals for large volume detectors due to the high concentration of dislocation walls (sub-grain boundaries), the presence of Te inclusions, Zinc segregation¹³⁻¹⁹. In addition to the material

imperfections of CdZnTe single crystals, the melt processing growth method and post-growth thermal annealing inflate the production cost of the crystals²⁰.

Recently, Lead halide perovskite materials have attracted substantial attention, not only because of the application in photovoltaics, light emitting diodes (LEDs), and photodetectors, but also because of the deployment in radiation detection. Perovskite materials possess impressive optical and electrical properties, including long charge-carrier diffusion lengths, tunable bandgaps (1.43 eV~2.3 eV), low defect density, and high defect tolerance²¹⁻²⁴. Due to the presence of Pb, Br or I atoms, perovskite detector possesses large atomic number (Z) for strong stopping power, making them attractive for radiation detection. Additionally, the cheap raw materials coupled with low-cost solution growth methods to still achieve a large electron and hole mobility-lifetime ($\mu\tau$) product make perovskite materials highly competitive with CdZnTe²⁵. Few significant works using perovskites for gamma-ray detection have been reported over the past few years. Sergii Y. et al. fabricated the formamidinium lead triiodide (FAPbI₃) single crystal detector capable of sensing 59.6 keV ²⁴¹Am signal²⁶. However, unintentional doping in perovskite materials makes the measured resistivities smaller than those calculated from intrinsic charge concentration²⁷. The resistivity of hybrid perovskite can be further increased by improving the crystal quality or exploring other compositions. For example, Wei H. et al. utilized the weak p-doping property of MAPbBr₃, and partially replace Br⁻ with Cl⁻ to n-dope MAPbBr₃ and reduce the intrinsic carrier concentration²⁸. The dopant-compensated MAPbBr_{2.94}Cl_{0.06} alloy has over tenfold improved bulk resistivity of $3.6 \times 10^9 \Omega \text{ cm}$, compared to $2 \times 10^8 \Omega \text{ cm}$ of pristine MAPbBr₃. Alloying also improves the hole mobility to $560 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, resulting in a higher $\mu\tau$ product of $1.8 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1}$. With the deposition of a guard ring, the detector can obtain ¹³⁷Cs energy spectrum with a resolution of 6.5%. This work also proved that single-crystalline hybrid perovskites have good

stability against heat and moisture. But all-inorganic perovskite in principle may have better moisture/ temperature stability, because of the alternation of organic cations by Cs cations^{29, 30}. Remarkable progress has been achieved by using Bridgman method to grow large-size and high-quality CsPbBr₃ single crystals³¹⁻³⁴. For example, Constantinos C. et al. used equimolar amounts of PbBr₂ and CsBr to synthesize orthorhombic CsPbBr₃ single crystals in the sealed fused silica ampule at 600 °C³¹. In 2018, Hui Y. et al. applied modified Bridgman method to synthesize CsPbBr₃ single crystal with hole and electron $\mu\tau$ product of $1.34 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1}$ and $8.77 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1}$, respectively³⁵. The CsPbBr₃ detectors can achieve an energy resolution of 3.9% for 122 keV ⁵⁷Co gamma-ray and 3.8% for 662 keV ¹³⁷Cs gamma-ray at room temperature. However, the Bridgman melt-growth method needs to raise the temperature to over 500 °C and go through multiple purification processes to purify the raw material which significantly increase the fabrication cost to a level that is not necessarily lower than that of CdZnTe. This complex high-cost method drives the research of simple and inexpensive low-temperature solution growth methods which could also synthesis high-quality crystals for the application of gamma-ray detection. There are few works demonstrating solution-grown CsPbBr₃ single crystals^{36, 37}. Yevgeny R. et al. and Hongjian Z. et al. employed antisolvent vapor assisted (ASV) method by using acetonitrile (MeCN) or methanol (MeOH)^{38, 39}. Dmitry N. et al., Fangbao W et al., and Hongjian Z et al. used DMSO /DMF /cyclohexanol (CyOH) mixed solvent to widen the temperature range of solubility drop, and employed inverse temperature crystallization (ITC) method to grow large CsPbBr₃ single crystals⁴⁰⁻⁴².

Here we report a simple additive assisted inverse temperature crystallization method to achieve high quality CsPbBr₃ single crystals. The addition of choline bromide (CB) into the precursor solution enables the growth of large, cuboid shape CsPbBr₃ crystals while using low

purity raw materials. In comparison with crystals grown without CB, the density of traps in the crystals using this modified method are suppressed by an order of magnitude. The detectors made utilizing the solution-grown perovskite CsPbBr₃ single crystals acquired an energy spectrum from a cesium-137 (¹³⁷Cs) source with a resolution of 5.5% at 662 keV.

Results and Discussion

Pioneering studies have reported that lead halide perovskite, such as MAPbX₃ (X =Br and I), FAPbX₃, and CsPbBr₃, show retrograde solubility in solvents like gamma-butyrolactone (GBL), N,N-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO)^{40, 43-45}. Therefore, we adopt the inverse temperature crystallization (ITC) method which crystallizes the CsPbBr₃ through elevating the temperature of the solution. For growth without additive, standard precursor solution was made by dissolving CsBr and PbBr₂ into DMSO solvent, as DMSO solvent has higher solubility limits for CsBr and PbBr₂ compared with GBL and DMF. For growth with CB additive, CB was further added into standard precursor solution. CsPbBr₃ single crystals were synthesized by gradually increasing the heating temperature. The molar ratio between PbBr₂ and CsBr is ~2:1 to obtain the pure CsPbBr₃ phase. It is reported that three possible products can be synthesized by tuning the PbBr₂: CsBr ratio^{37, 40, 46}. If PbBr₂: CsBr is less than 1.5: 1, Cs-rich precipitate (Cs₄PbBr₆) will be the main product. If PbBr₂: CsBr is larger than 4: 1, a Pb-rich precipitate (CsPb₂Br₅) tends to be the primary product. This can be explained by that CsBr has lower solubility in DMSO than PbBr₂, while the formation of PbBr_n⁽²⁻ⁿ⁾ by adding more PbBr₂ increases the solubility of CsBr.

Figure 1. (a) CsPbBr_3 structure at different temperature. The transition from cubic to tetragonal happens at 130°C , and transition from tetragonal to orthorhombic happens at 88°C . (b) Bar shape CsPbBr_3 single crystal grown without CB. The left inset indicates the miller indices of each surface, and the right inset is the photograph of crystals in solution. (c) Cuboid shape CsPbBr_3 single crystal grown with CB. The left inset indicates the miller indices of each surface, the right inset is the photograph of crystals in solution, and the bottom of the vial is a Si-wafer to make a flat bottom.

CsPbBr_3 undergoes phase transitions from cubic to tetragonal at 130°C , and from tetragonal to orthorhombic at 88°C ^{47, 48}. Figure 1(a) displays its crystal structures at different temperature range. It possesses cubic structure (space group $\text{Pm}\bar{3}\text{m}$) at temperature higher than 130°C . Upon cooling down below the first transition point, the PbBr_6 octahedra will rotate in the

ab plane, forming tetragonal structure (space group $P4/mbm$). As the crystal is cooled past 88°C , the structure transforms to an orthorhombic structure (space group $Pbnm$, $a = 8.20\text{ \AA}$, $b = 8.26\text{ \AA}$, $c = 11.78\text{ \AA}$), involving PbBr_6 octahedra tilt away from c axis. Therefore, careful design of the growing temperature is required to avoid the defects and stress induced by phase transition⁴⁹. In this work, we chose 85°C as the growth temperature to ensure crystals keep growing at orthorhombic phase and thus there is no phase transformation once they are cooled down to room temperature.

Although we can control the crystal phase through growth temperature, the crystals grown from regular precursor solution (containing CsBr , PbBr_2 , and DMSO) still suffer from bar shape, which is in accordance with previous reports^{39, 50, 51}. Figure 1(b) presents the photo of a bar shape CsPbBr_3 single crystal. The small bar shape makes it difficult to fabricate a practical detector. The bar shape mainly results from the asymmetric growth rate along different directions. To identify the various growth directions, we performed X-ray diffraction (XRD) and found the exposed facets to be (110) , $(1\bar{1}0)$, and (002) , as shown in the left inset of Figure 1(b-c). The crystal is elongated along $[002]$ direction, which can be attributed to the fastest growth rate along this direction.

To investigate the reason that CsPbBr_3 tends to grow faster along $[002]$, we employed an attachment energy (AE) model developed by Hartman and Bennema, which has been widely used to predict crystal shape⁵²⁻⁵⁴. The attachment energy of a facet (hkl) is defined as the released energy when a new layer of atoms is attached to the surface of the crystal. The energy is determined by the bonding strength and the number of bonds at a given face. Therefore, faces with a larger attachment energy have faster growth rates. Here, in CsPbBr_3 orthorhombic structure, we mainly analyze $(1\bar{1}0)$ and (002) direction since the similarity in structure and growth rate of (110) and $(1\bar{1}0)$. Figure 2(a) and (b) display the facets along $[002]$ and $[1\bar{1}0]$, respectively. Two types of planes

are presented normal to both directions. In particular, PbBr_2 terminated (002) facet with Pb: Br ratio of 2: 1 and CsBr terminated (004) facet with Cs: Br ratio of 1: 1 are presented normal to [002] direction. CsBr terminated ($1\bar{1}0$) facet with Cs: Br of 1: 1, and PbBr_2 terminated ($2\bar{2}0$) facet with Pb: Br of 2: 1 are presented normal to $[1\bar{1}0]$ direction. Here we employed first principle calculations by using CASTEP program which has plane-wave pseudopotential method to calculate the AE of these four facets⁵⁵. The average AE of facets normal to the [002] direction was calculated to be 0.115 eV, 0.145 eV on (002) and 0.078 eV on (004). The average AE of the facets normal to $[1\bar{1}0]$ direction was calculated to be 0.095 eV, 0.084 eV on ($1\bar{1}0$) and 0.110 eV on ($2\bar{2}0$). The greater average AE calculated for facets along the [002] direction is congruent with the faster growth observed in the [002] direction of bar shaped crystals grown with no additives.

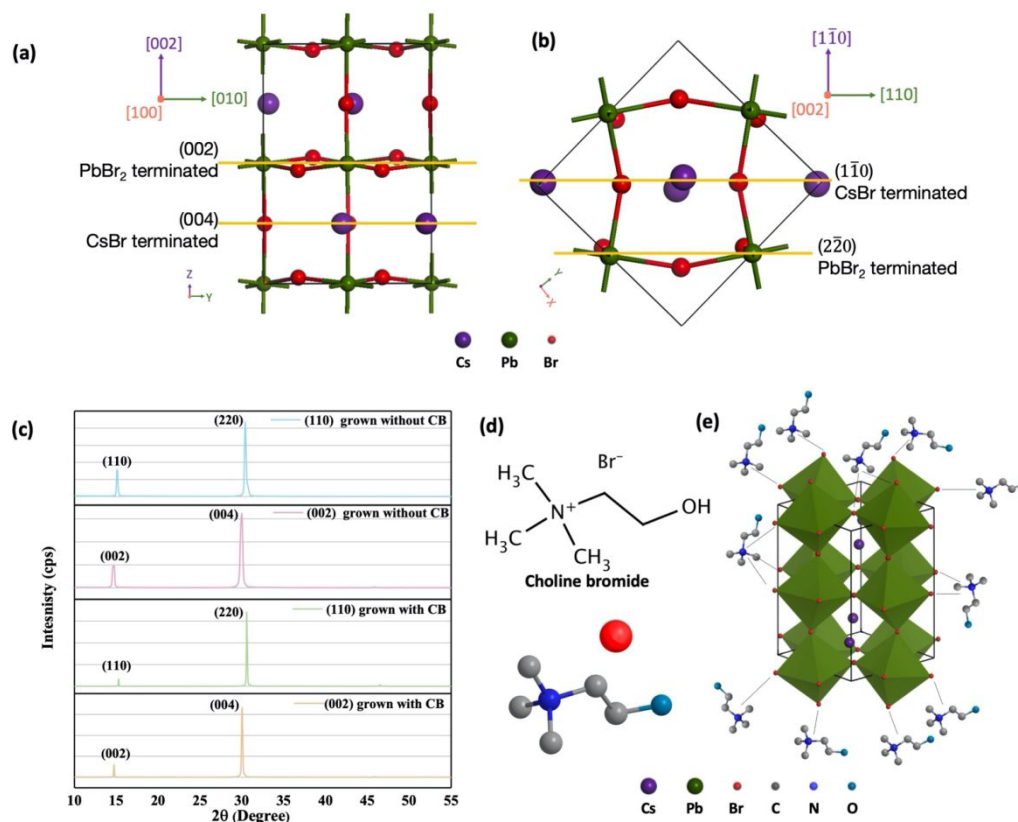

Figure 2. (a) Side view of the orthorhombic CsPbBr₃ unit cell structure. The yellow lines indicate (002) and (004) plane. (b) Top view of the unit cell structure. The yellow lines indicate (1 $\bar{1}$ 0) and (2 $\bar{2}$ 0) plane. (c) XRD pattern of CsPbBr₃ single crystal grown with and without CB. (d) Molecular structure of choline bromide (CB). (e) Schematic illustration of CB assisted CsPbBr₃ single crystal growth.

It is more favorable to have cuboid shape crystal to allow for easier fabrication and characterization of a detector. In this work, we found out that the addition of CB into precursor solution, containing CsBr, PbBr₂, CB and DMSO, could alter the resulting shape of the CsPbBr₃ crystals from a bar shape to a cuboid shape. As shown in Figure 1(c), the cuboid crystal could maintain good transparency. The exposed facets were again characterized by XRD (Figure 2(c)), and they all keep the same as the bar-shape crystal (left inset of Figure 1(c)). Therefore, CB suppresses the [002] crystal growth rate without changing the CsPbBr₃ structure. Here we propose a possible mechanism by which CB is capable of altering the anisotropic growth typically observed for CsPbBr₃ single crystals. As shown in Figure 2(d), CB is composed of quaternary ammonium group, a bromide ion, and a hydroxyl group. The positively charged quaternary ammonium group can coordinate with Br ions by electrostatic interactions, adsorb on the growing crystal, and subsequently block Cs⁺ or Pb²⁺ attaching on the crystal growth site, illustrated in Figures 2(e). Therefore, the crystal growth rate was reduced from 1.25 mm³/h in the solution without CB to 0.34 mm³/h in the solution with CB. It should be noted that it is possible for choline molecules to coordinate with not only the (002) surface but also the (110)/ (1 $\bar{1}$ 0) surfaces, due to the equal plane density of Br ions. However, the change from cuboid shape to bar shape suggests growth of the [002] is more inhibited than [110]/ [1 $\bar{1}$ 0]. Because of the attachment of CB on those facets, the

absorbing energy difference between these facets disappears. Therefore, crystals lose the preferred crystal growth direction. Here we demonstrate the addition of CB additives can be utilized to alter crystal growth to control the resulting crystal shape and produce attractive cuboid CsPbBr₃ solution processed single crystals.

We further investigated if additive-assisted method could improve the crystal quality. To understand how CB influences the defect density within the crystals, the trap density of states (tDOS) of CsPbBr₃ single crystal grown with and without CB was measured by thermal admittance spectroscopy, and the result is shown in Figure 3(a). The CB-assisted growth process proves capable of drastically reducing the defect density of resulting crystals by roughly two orders of magnitude at low level traps states and approximately one order of magnitude at deeper trap states. In order to best characterize the quality of the crystal bulk, both types of crystals without obvious macroscopic defects were chosen in this measurement. Also, the surface of crystals was polished by sandpaper and passivated by (C₈H₁₇NH₃)₂SO₄ to eliminate any influence arising from differences at the surface⁵⁶. This confirms that the CB-assisted ITC process is highly advantageous for not only altering the shape of the crystals, but also growing high-quality single crystals with reduced defect density.

It should be also noted that the concentration could impact the crystal defect density. Because the CB suppresses growth rate and decrease defect density by adsorbing on the surface of growing crystal. Small amount of CB could not offer enough quaternary ammonium groups if the size of the crystal is large. Therefore, we found obvious macroscopic defects at the edge of crystal due to the insufficient CB. In this work, the concentration of CB was 0.09 mol/L CB, and typical size of crystal at this concentration is around 9 mm × 9 mm × 3 mm.

The improved quality of crystals grown using the CB-assisted ITC process is also evident in the resulting performance of the fabricated detectors. Detectors are fabricated by depositing electrodes, gold (Au) cathode and gallium (Ga) anode, at the center of the crystals to suppress the leakage current flowing at the side surface which could otherwise corrupt the signal, Figure 4(a). It is important to note that due to CsPbBr_3 being an intrinsically p-type material, Ga is chosen as the anode in order to decrease the dark current density under high electrical field by forming a Schottky contact at the Ga side under reverse bias ²¹.

It is well reported that when under an electric field, ions within perovskite materials can migrate and result in a myriad of problems for all kinds of devices that need to be biased^{57, 58}. The presence of point defects, lattice distortion, and dislocations within the bulk of single crystals can facilitate ion migration⁵⁹. Significant ion migration results in unstable dark current, known as dark current drift. Dark current drift can be particularly problematic for perovskite materials used in gamma-ray detection due to the extremely high applied voltage bias accelerating the ion migration process. Therefore, we can indirectly evaluate the crystal quality by assessing the dark current drift of the detectors. Detectors were biased under a large electric field of 910 V/cm and the dark current was recorded for one hour, as shown in Figure 3(b). The dark current drift of detectors is effectively suppressed when using crystals grown using the CB-assisted method, resulting in a drift of only 6 nA/ cm² over one hour with a starting dark current of 74 nA/ cm². In contrast, the dark current density of the resulting detector without using the CB-assisted method started at 135 nA/ cm² and drifted to 1703 nA/ cm². The large dark current drift of the detector without CB is in consistent with the greater defect density shown in Figure 3(a).

The mobility-lifetime ($\mu\tau$) product is one of the important figures of merit for gamma-ray detectors. According to Hecht equation, the mobility-lifetime is an intrinsic parameter of a material

that determines the charge collection efficiency⁶⁰. In this work, we use a 20 keV X-ray source to measure photocurrent at various voltages. Due to the high atomic density of CsPbBr₃, the mean free path of 20 keV X-rays is only ~30 μm (**Linear** attenuation coefficient-Photon energy plot in Supplementary Figure 4). This means that the carriers are mainly generated near the surface of the 2.5 mm thick crystal. The μτ product is obtained by fitting the photocurrent I to the modified Hecht equation:

$$I = \frac{I_0 \mu \tau V}{d} \left(1 - \exp \left(- \frac{d^2}{\mu \tau V} \right) \right) \quad (1)$$

where d is the thickness of the detector, I₀ is the saturated photocurrent, and V is the voltage bias applied to the detector. The hole and electron μτ products of the detector using a crystal grown from the CB-assisted method are then calculated to be 1.80×10⁻³ cm² V⁻¹ (Figure 3(c)) and 0.73×10⁻³ cm² V⁻¹ (Figure 3(d)), respectively. In contrast, the calculated hole and electron μτ products of the detector using a crystal grown from the standard ITC method are just 0.31×10⁻³ cm² V⁻¹ (Figure 3(e)) and 0.19×10⁻³ cm² V⁻¹, respectively (Figure 3(f)). The use of crystals grown by the new CB-assisted ITC process improves the μτ products of the resulting detector by approximately 4 times. The mobility of the detector fabricated with the CB-assisted crystals was also measured by the time-of-flight technique (ToF). The electron and hole mobility estimated by linear fitting τ_{transit} verse 1/V are 181 cm² V⁻¹ s⁻¹ (supplementary Figure 5) and 56.5 cm² V⁻¹ s⁻¹ (Supplementary Figure 6), respectively. These values are comparable to the mobility of CsPbBr₃ crystal by Bridgman growth approach³⁵.

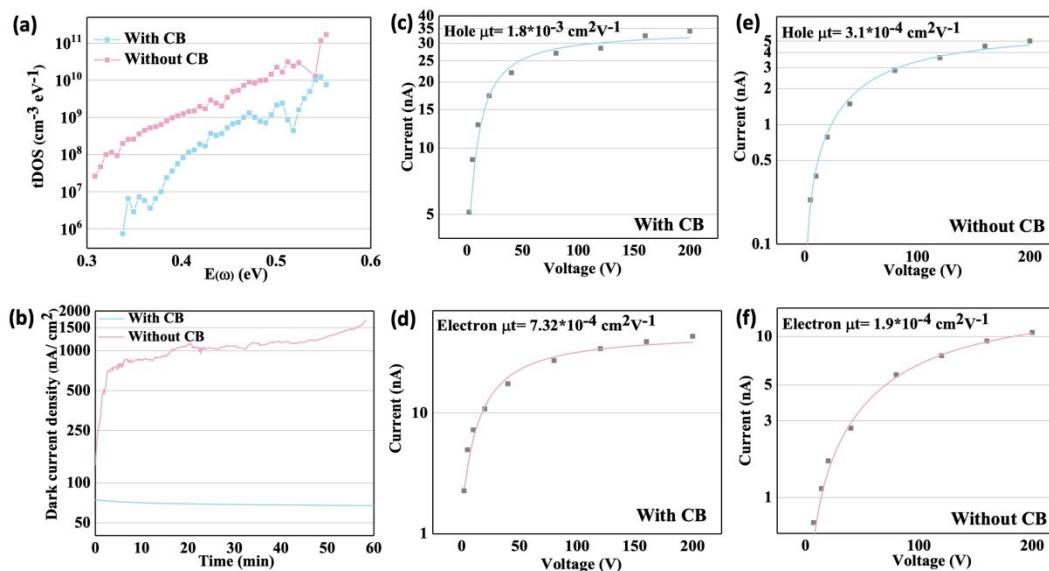

Figure 3. (a) $tDOS$ and (b) dark current density as function of time of detectors with and without CB. (c) hole and (d) electron $\mu\tau$ product of detector with CB by Hecht equation fitting. (e) hole and (f) electron $\mu\tau$ product of detector without CB by Hecht equation fitting.

The high atomic density, low trap density, stable dark current, and large $\mu\tau$ product suggest that CB-assisted CsPbBr₃ single crystal detectors have immense potential for gamma-ray spectroscopy. To this end, we tested gamma-ray spectral performance under exposure to a ¹³⁷Cs source emitting 662 keV gamma-rays. For the measurement, the ¹³⁷Cs source was placed on the Au cathode side of CsPbBr₃ detector (4.5 mm × 4.5 mm electrode area, 2.5 mm thickness), which was connected to a Charge Sensitive Preamplifier (CAEN A1422) and a CAEN N6724 Digitizer with embedded Digital Pulse Processing firmware. The typical resolution acquired by the CB-assisted CsPbBr₃ detector is 9%~10%, while the best resolution acquired at room temperature is

5.5% (Figure 4(b)) with bias of 2700 V/cm and collection time of 15 min. It should be noted that low purity grade raw materials directly purchased from vendor were used to grow the single crystal, which could potentially be a source of undesirable impurities in the final crystal. It is expected that the performance and resolution of the detector can be further improved if high purity raw materials are used³⁵. The elevated Compton plateau in Figure 4(b) can be attributed to the small volume of the crystal, resulting in a large fraction of scattered photons likely escaping from the detector. Therefore, future work can be focused scaling the additive assisted ITC solution growth process to produce larger crystals.

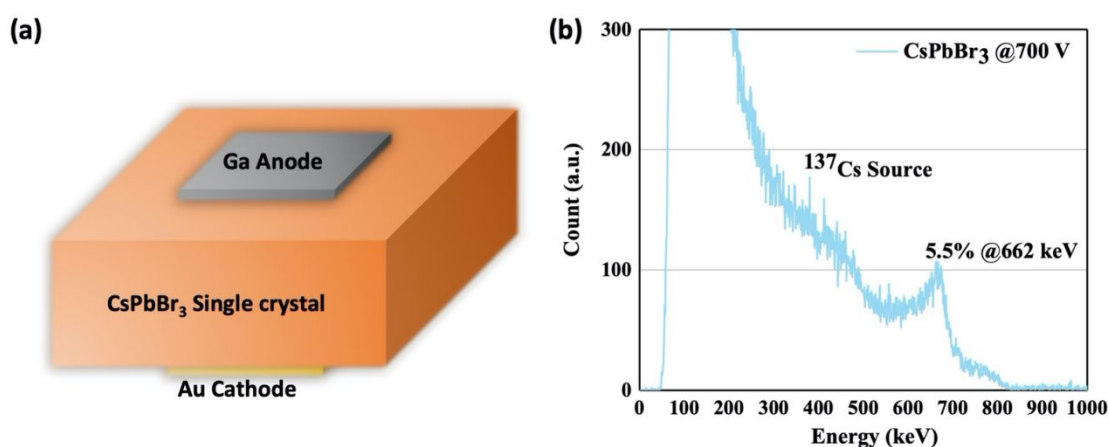

Figure 4. (a) Schematic of detector structure (4.5 mm × 4.5 mm electrode area, 2.5 mm thickness). (b) 662 keV ¹³⁷Cs spectrum acquired by CsPbBr₃ single crystal under 700 V.

In conclusion, we demonstrate that high quality CsPbBr₃ single crystals can be synthesized by using our new additive-assisted ITC solution growth method. The addition of choline bromide into the precursor solution is able to mediate the crystallization process to suppress the fast growth along [002] direction, thus reforming the shape of the resulting crystal from bar to cuboid. CB-

assisted grown CsPbBr₃ single crystals also exhibit lower trap density, and superior dark current stability, indicative of a higher quality crystal compared to those grown without CB. The CB-assisted CsPbBr₃ single crystal detector also demonstrates excellent charge transport capabilities. Estimated by Hecht equation, the electron and hole mobility-lifetime ($\mu\tau$) products are $0.73 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1}$ and $1.80 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1}$, respectively. More importantly, the CB-assisted CsPbBr₃ single crystal is able to deliver a 662 keV ¹³⁷Cs spectrum with resolution of 5.5%, which is, to date, the highest resolution acquired by a solution grown perovskite detector.

Experimental Section

Chemicals and Reagents: Low purity PbBr₂ ($\geq 98\%$), CsBr ($\geq 99.9\%$), dimethyl sulfoxide (DMSO, $\geq 99.9\%$) were purchased from Sigma-Aldrich. Choline Bromide (CB, $\geq 98\%$) was purchased from TCI America. All raw materials and solvent were not further purified before using.

Preparation of precursor solution: Standard CsPbBr₃ precursor solution was obtained by dissolving CsBr (4.8 mmol) and PbBr₂ (9.6 mmol) with a molar ratio of 1:2 in 5.3 mL DMSO solution. Precursor solution with CB was obtained by further adding 0.5 mmol CB to the standard precursor solution. The precursor solutions were heated to 80 °C to accelerate the dissolution of the raw material. Transparent solutions could be obtained after 5-10 hours. Solutions were then filtered with a 0.2 μm pore size PTFE filter.

Growth of CsPbBr₃ single crystal: Small CsPbBr₃ seeds were first prepared with fresh supersaturated precursor solution at 85 °C. Small and transparent seeds were then picked and put on the bottom of the vials for large crystal growth. The temperature of the vials was set at 80 °C initially with an increasing rate of 1 °C/ h, and was eventually maintained at 85 °C. Vials were covered with glass slides to avoid fast evaporation of the DMSO. So the growth driving force is

supersaturation achieved by slow evaporation of DMSO solvent. After 120~170 hours, a centimeter-sized single crystal was picked from the solution, followed by wiping the residue solution on the surface.

Detector fabrication: The resulting orange CsPbBr₃ crystals were fine polished with 14,000 grit polishing paper by the polishing machine. The dust on the polished surface was removed by nitrogen flow and washed by Toluene. The surface of the crystals was then spin-coated by (C₈H₁₇NH₃)₂SO₄ for 2500 rpm to convert perovskite into lead sulfate (PbSO₄) passivation layer, which is insoluble in water and large band gap. More details of the passivation can be found in our previous work⁵⁶. One side of the crystals was deposited with gold (Au) with a thickness of 50 nm by thermal evaporation. The other side was applied with gallium (Ga).

Characterization: The X-ray diffraction (XRD) was characterized by Rigaku MiniFlex X-ray diffractometer. Steady-state PL measurement was performed on a Horiba iHR320 imaging spectrometer at 25 °C. The excitation source was a 325 nm pulse laser. Dark current was measured by a Keithley 2400 Source meter with a sampling rate of 500 ms per point. Trap density of states (tDOS) was measured by admittance spectroscopy method, the device was kept dark during the entire test. The test was performed by an Agilent E4980A Precision LCR Meter. The energy profile of tDOS was calculated from the equation $N_T(E_\omega) = -\frac{1}{qk_B T} \frac{\omega dC V_{bi}}{d\omega W}$, where q is the elementary charge, ω is the angular frequency of the ac bias, C is the specific capacitance of the device, T is the temperature, k_B is the Boltzmann constant, W is depletion width of the device, V_{bi} is the built-in potential. The energetic demarcation is derived by $E_\omega = k_B T \ln \frac{\omega_0}{\omega}$, where ω_0 is the attempt-to-escape frequency. Mobility is obtained by the time-of-flight (ToF) technique. The excitation source was a 325 nm pulse laser. The photocurrent induced by laser was first fed into a SR-570 current pre-amplifier, and then recorded with an Agilent DSO-X 3104A digital oscilloscope.

Mobility-lifetime ($\mu\tau$) product was fitted from modified Hecht equation $I = \frac{I_0\mu\tau V}{d} \left(1 - \exp\left(-\frac{d^2}{\mu\tau V}\right)\right)$. The photocurrent is generated by a 20 keV X-ray beam. Sensitivity was measured under a different dose rate of 60 keV X-ray source. The radiation dose rate was calibrated by a RaySafe X2 dosimeter. Gamma-ray spectrum is collected by a Charge Sensitive Preamplifier (CAEN A1422), a CAEN N6724 Digitizer, and its embedded Digital Pulse Processing firmware⁶¹.
