Unique selectivity of rare-earth metal ambiphilic carbenes towards organic molecules and novel reactivity patterns with isonitriles†

Fuxiang Chai,^a Weikang Wu,^a Thayalan Rajeshkumar,^d Zeming Huang,^b Qingbing Yuan,^b Yun Wei,^a Laurent Maron^b*^d and Shaowu Wang^b*^{bc}

Studies on the chemistry of highly active rare-earth (RE) metal ambiphilic carbenes face challenges due to the lack of appropriate model molecular platforms because the corresponding ambiphilic carbenes have empty p-orbitals. Here, the synthesis of novel multi-chelated amidate rare-earth metal pincer complexes bearing ambiphilic carbenes is realized by using indol-2-yl-based ligands. The ambiphilic carbene (indol-2-yl carbon) of these complexes is extremely active and shows unique selective reactivity towards various organic molecules including carbodiimides, imine, diphenyldiazomethane, aluminum alkyls, 9-BBN and isonitriles, which demonstrate a range of unprecedented reactivity patterns such as formal [2 + 2] cyclometallation, [3 + 3] annulation, and aza-[4 + 1] annulation, while unprecedented aza-[4 + 1 + 1] annulation products were isolated from the reactions of the rare-earth metal complexes bearing electrophilic carbenes and strongly polarized metallacyclopropanes with 2,6-dimethylphenylisonitrile. Such reactivities differ sharply from those of common transition-metal complexes with the corresponding substrates. The electronic and steric effects of the ligands and the effects of central metal ions on the reactivity patterns were investigated both computationally and experimentally.

Introduction

The design and synthesis of new ligands for catalysis is among the ever-green research areas in modern chemistry.¹ Particularly, organometallic complexes containing pincer ligands are well known for their exceptional thermal stability, distinctive reactivity and wide applicability in catalysis.² The reactivity of pincer complexes can be manipulated through modulations of substituents on the donor groups or introduction of diverse connections between the central backbone and donor groups.³ Thus, various symmetric pincer ligands bearing different backbones such as phenyl,⁴ pyridyl,⁵ pyrrolyl,⁶ carbazoyl,⁷

carbon or heteroatom-bridged diaryl⁸ and all-carbon carboblong pincer ligands⁹ have been developed. Our group has been engaged in the development of pincer-type rare-earth metal complexes featuring non-symmetric indol-2-yl-based ligands with development of new catalysis for the transformations of various organic molecules.¹⁰ On the other hand, amidate metal complexes demonstrated distinctive reactivity and catalytic performance,¹¹ with applications in olefin polymerization,¹² copolymerization,¹³ ester polymerization,¹⁴ and alkene hydroamination.¹⁵ Despite these advances, multi-chelated amidate pincer ligated complexes bearing both ambiphilic carbenes and nucleophilic alkyls have so far been unreported and their reactivity remains elusive.

Singlet carbenes in late transition-metal complexes are known to have lone pair electrons donated to the metal center and an empty p-orbital to accept d-electrons from the metal to form π -backbonding (Scheme 1).¹⁶ A recent study indicated that the p-orbital receptor properties of these carbenes can be effectively harnessed.¹⁷ Given that rare-earth metal ions have no d-electron to form π -backbonding, rare-earth metal complexes bearing such electrophilic carbenes might possess unique reactivity for application in catalysis and activation of small molecules. However, the synthesis of rare-earth metal electrophilic carbene complexes has just been realized until very recently, and 1,1-alkyl or 1,1-H(D) migratory reactions, and unique reactivity patterns towards pyridine derivatives were found with these complexes (Scheme 1).^{11g,18,19} The chemistry of

Scheme 1 Bonding and reactivity of the RE complexes bearing indol-2-yl ligands.

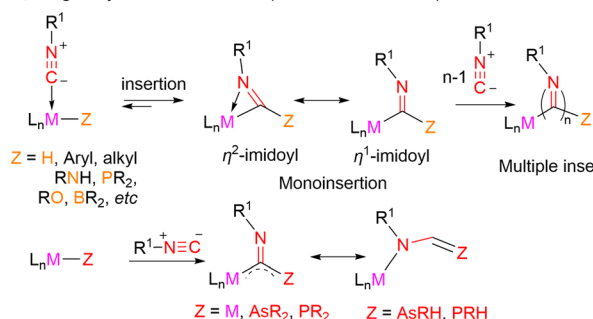

rare-earth metal complexes bearing an electrophilic carbene is far less developed in comparison with those of late transition metals.

N-Heterocyclic carbenes (NHCs) are one of the most widely used ligands and catalysts for their strong electron-donating and Lewis basic properties, as well as stable bonding with metals, and easy adjustment.²⁰ Cyclic (alkyl)(amino)carbenes (CAACs) are receiving extensive attention due to their ambiphilic character.²¹ CAACs have also been applied in various fields such as transition-metal catalysis,²² and light emitting materials as CAAC-Cu complexes.²³ Additionally, isolated CAACs have high thermal stability that can be utilized in stabilizing paramagnetic substances and activating small molecules (such as CO,²⁴ P₄,²⁵ H₂ (ref. 26) and NH₃ (ref. 26)). Following these pioneering studies of the CAACs, other types of ambiphilic carbenes have been developed and applied in catalysis or activation of small molecules.²⁷ However, these

carbenes have only been used as supporting ligands in rare-earth metal chemistry, and studies on the chemistry of rare-earth metal complexes bearing both ambiphilic carbene and nucleophilic alkyl have to overcome some challenges including the lack of a model molecular platform due to their high activity and instability.

The reactions of isonitriles with transition metal compounds have been extensively studied with findings of cyclization reactions, migration insertion and multi-component reactions.²⁸ The insertion of isonitriles into the metal-element σ bond will result in the formation of complexes having η^1 - or η^2 -imidoyl (iminoacyl) (Scheme 2);²⁹ or the η^1 or η^2 formyl complexes;³⁰ or the bridged μ^2 -CNR ligands. The insertion of isonitriles into the multiple M=C carbon bond will form metallocyclopropanes (η^2 ketenimine) or κ^1 ketenimine;^{31,32} insertion of isonitrile into the Sc-C bond of aryl rare-earth metal complexes generates imidoys, these complexes participate in

Scheme 2 Reaction modes of isonitrile with metal complexes.

further transformation reactions and then form an unusual indoline scandium with another isonitrile molecule.^{32,33} These findings enrich the methods for constructing chemical bonds in organic synthesis. However, the reactivity pattern of rare-earth metal complexes having both ambiphilic carbenes and nucleophilic carbons with isonitriles remains elusive.

Herein, we report the design, synthesis and reactivity study of homodinuclear pincer-type rare-earth metal alkyl complexes featuring novel multi-chelated 1-amidate-3-imino functionalized indol-2-yl ligands, and reactivity study of rare-earth metal complexes bearing electrophilic carbon and strongly polarized metallacyclopropanes with 2,6-dimethylphenylisonitrile. The RE-C_{carbene} bonds of these complexes exhibit unique selective reactivity towards electrophiles and nucleophiles, which could be associated with the ambiphilic carbene nature of the indol-2-yl carbon as revealed by DFT calculations and experimental results.

Results and discussion

Synthesis and characterization of multi-chelated amidate homodinuclear pincer rare-earth metal complexes bearing ambiphilic carbene and nucleophilic alkyl

The reactions of the ligand precursors H₂L^{Ad} [L^{Ad} = 1-[(N-2,6-ⁱPr₂C₆H₃)NCOCH₂]-3-(C₁₀H₁₅N=CH)-C₈H₄N, Ad = adamantyl, C₁₀H₁₅]; H₂L^{Dipp} [L^{Dipp} = 1-[(N-2,6-ⁱPr₂C₆H₃)NCOCH₂]-3-(2,6-ⁱPr₂C₆H₃N=CH)-C₈H₄N; Dipp = 2,6-ⁱPr₂C₆H₃]; H₂L^{DMA} [L^{DMA} = 1-[(N,N-Me₂)NCOCH₂]-3-(2,6-ⁱPr₂C₆H₃N=CH)-C₈H₄N] (see the ESI†) with RE(CH₂SiMe₃)₃(THF)_n (RE = Gd, Dy, Y, Er, Yb, Lu) in a 1:1 stoichiometric ratio at room temperature in tetrahydrofuran (THF) or toluene for 3 h produced the corresponding novel multi-chelated amidate homodinuclear pincer rare-earth metal complexes [η¹:η¹:(μ-η¹:η²)-L^{Ad}RE(CH₂SiMe₃)(-THF)]₂ [RE = Gd(**1a**), Dy(**1b**), Y(**1c**), Er(**1d**), Yb(**1e**), Lu(**1f**); [η¹:η¹:(μ-η¹:η²)-L^{Dipp}RE(CH₂SiMe₃)(THF)]₂ [RE = Y(**2a**), Er(**2b**), Yb(**2c**), Lu(**2d**); [η¹:η¹:(μ-η¹:η²)-L^{DMA}RE(CH₂SiMe₃)(THF)]₂ [RE = Y(**3a**), Er(**3b**), Yb(**3c**), Lu(**3d**)] in high yields (Scheme 3, Fig. 1 and S52–S65 in the ESI†). All complexes were fully characterized by spectroscopic methods and elemental analyses, and their structures were confirmed by single-crystal X-ray diffraction.

The diamagnetic complexes **1c**, **1f**, **2a**, **2d**, **3a**, and **3d** were further characterized by NMR spectroscopy. In the ¹H NMR spectrum of complex **1c**, the signal centred at −0.23 ppm could be assigned to the resonances of the methylene protons of the CH₂SiMe₃ group, and is comparable with the resonance at −0.34 ppm (s, 2H) attributed to the protons of the methylene of the CH₂SiMe₃ in the 2-amidate indolyl yttrium complex.^{4b} Unlike complex **1c**, the methylene protons of the Y-CH₂SiMe₃ in complex **2a** gave doublet resonances centred at −0.16 ppm (²J_{Y-H} = 8.0 Hz). Complex **3a** exhibits more pronounced coupling of yttrium ion nucleus with the protons of the CH₂SiMe₃, resulting in doublet resonances at −0.06 ppm (²J_{Y-H} = 15.0 Hz) and −0.16 ppm (²J_{Y-H} = 15.0 Hz). In addition, the corresponding methylene protons of the lutetium complexes were found to resonate at −0.37 ppm, −0.66 ppm (**1f**); −0.22 ppm, −0.37 ppm (**2d**); and −0.24 ppm, −0.32 ppm (**3d**), respectively, suggesting that the substituents of the ligands and coordinated THF might prevent the Lu-C_{CH₂SiMe₃} bonds from free rotation, thus showing different proton resonances for the alkyls (−CH₂SiMe₃). The signal centred at 200.4 ppm in the ¹³C{¹H} NMR spectrum of **1c** is attributed to the resonance of the carbon of the indol-2-yl coupled with the yttrium ion nucleus with ¹J_{Y-C} = 40.0 Hz, which can be compared with previously reported data.^{10a,11g,18,19} The signal centred at 201.8 ppm assigned to the indol-2-yl carbon (C_{2-ind}) in the ¹³C{¹H} spectrum of **2a** is coupled to the yttrium ion nucleus (¹J_{Y-C} = 50.0 Hz), moving downfield as compared to that in **1c**. The signal centred at 201.3 ppm (¹J_{Y-C} = 50.0 Hz) in the ¹³C{¹H} spectrum of **3a** can be compared with the literature data (indol-2-yl carbon of L*RE(CH₂SiMe₃)₂(THF)_x (L* = 1-(2-C₄H₇OCH₂)-3-(2,6-ⁱPr₂C₆H₃N=CH)C₈H₄N) at 201.8 ppm).¹⁸ While the corresponding carbon resonances in the lutetium complexes **1f**, **2d**, **3d** shift even more downfield to 206.7, 209.2, and 210.9 ppm, respectively, these resonances for the indol-2-yl carbon atoms fall in the range of singlet metal carbenes.^{34a}

X-ray analysis reveals that the amidates in complexes **1**, **2** and **3** adopt the μ-η¹:η² mode with the oxygen atoms of the amidates bridging two rare-earth metal ions; the amidates bond with one of the metal ions in η² mode, and the imino-functionalized indol-2-yl motifs bond with the central metal ions in

Scheme 3 Synthesis of the homodinuclear rare-earth metal alkyl complexes **1–3**.

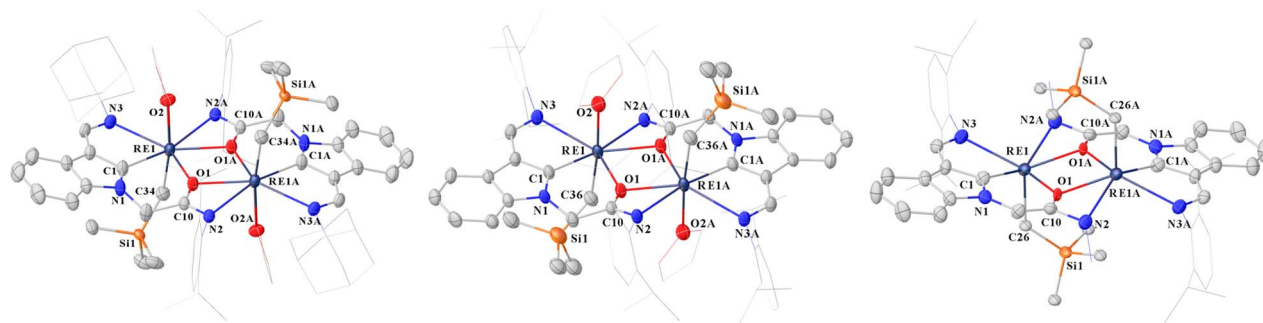

Fig. 1 Representative diagram for the complexes **1** (left), **2** (middle) and **3** (right) with thermal ellipsoids set at 30% probability level. All the hydrogen atoms are omitted, the diisopropylphenyl (Dipp) group and adamantyl (Ad) group are drawn in wireframe style for clarity. Selected bond lengths (Å) and selected bond angles (deg) can be read in the ESI†

a manner of $\eta^1:\eta^1$. Thus, the bonding modes of the ligands with the central metal ions can be described as $\eta^1:\eta^1:(\mu-\eta^1:\eta^2)$ on the basis of analysis of the structural bond lengths (Tables S1–S3 in the ESI†). The indol-2-yl carbon atoms, imino, amide groups and central metals are nearly coplanar in these rare-earth metal complexes. Obviously, two alkyl groups and two coordinated THF are present in the *trans*-form in complexes **1** and **2**. In the formation of complexes **1** and **2**, a sequence of indol-2-yl C–H activation and deprotonation is involved, while in the formation of complexes **3**, the activation of the indol-2-yl C–H and α C–H of the amide is involved to generate an amino-functionalized enolate anion bonding with the central metal ions in $\mu-\eta^1:\eta^2$ modes. This difference highlights the influence of substituents on the reactivity of the ligand precursors with $\text{RE}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$. It is found that the imino groups did not insert into the $\text{RE}-\text{C}_{\text{alkyl}}$ bonds, which was different from previous results.¹⁴ It's probably due to the stability of the multiple-chelated amide pincer structure, the steric hindrance of the adamantyl or the aryl groups and electron isomerization resulting in the enamido motifs (Scheme 3). Unlike complexes **1** and **2**, the central metal ions in complexes **3** have six-coordination-number due to the absence of THF coordination, and the two alkyl groups present in the *trans*-form.

The bond lengths of $\text{RE1}-\text{C}_{2\text{-ind}}$, $\text{RE1}-\text{O1}$, $\text{RE1}-\text{N1}$, $\text{RE1}-\text{N3}$ and $\text{RE1}-\text{O1A}$ in complexes **1a–1e**, **2a–2e** and **3a–3d** decrease with the decrease of ionic radius from Gd^{3+} to Lu^{3+} and Y^{3+} to Lu^{3+} (see Tables S1–S3 in the ESI†), which is consistent with the lanthanide contraction.^{34b} The distances of $\text{RE1}-\text{C}_{2\text{-ind}}$ [2.388(5) Å for **1c**; 2.348(7) Å for **1d**; 2.351(6) Å for **1e**; 2.320(6) Å for **1f**] in

complexes **1c–1f** are shorter than those of $\text{RE1}-\text{C}_{2\text{-ind}}$ [2.396(5) Å for **2a**; 2.367(3) Å for **2b**; 2.357(3) Å for **2c**; 2.335(3) Å for **2d**] of complexes **2a–2d**, probably due to the steric effects of the substituents on the ligands. The $\text{RE}-\text{C}_{2\text{-ind}}$ distances in **1** and **2** are shorter than those found in $\text{L}^*\text{RE}(\text{CH}_2\text{SiMe}_3)_2(\text{THF})_x$ [(RE = Y, $x = 1$, 2.452(6) Å; RE = Er, $x = 0$, 2.387(4) Å; RE = Dy, $x = 0$, 2.396(3) Å; $\{\text{L}^* = 1-(2-\text{C}_4\text{H}_7\text{OCH}_2)-3-(2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3\text{N}=\text{CH})\text{C}_8\text{H}_4\text{N}\}$],¹⁸ which can be attributed to coordination number and steric differences.

The O–C–N angles of the amides range from 115.0(3)° to 117.3(6)° in complexes **1** and from 116.3(3)° to 116.8(4)° in complexes **2**. These data are very close to those (115.3(9)° to 119.3(11)°) in the amide-functionalized N-heterocyclic carbene (NHC) rare-earth metal amido complexes.^{34c} The N–C–O angles of the amides (in the range of 107.7(4)° to 109.7(11)°) in complexes **3** are significantly smaller than the corresponding angles in complexes **1** and **2**, which can be attributed to the bonding differences between the amide in **1** or **2** and the amino-functionalized enolate in **3**.

DFT calculations show that the indol-2-yl carbon atoms have a natural charge of -0.253 in **1c** and -0.260 in **2a**, which are substantially smaller than those of carbon atoms of the alkyl ($-\text{CH}_2\text{SiMe}_3$) (natural charge of -1.711 in **1c** and -1.716 in **2a**) in the corresponding complexes (Table 1). The natural charge of the indol-2-yl carbon atoms in complexes **1** and **2** can be compared with that of -0.228 found in **8a**, which bears strongly polarized carboryne-based metallacyclopropanes.^{19b} This suggests some difference in reactivity and selectivity between the $\text{RE}-\text{C}_{2\text{-ind}}$ and $\text{RE}-\text{C}_{\text{CH}_2\text{SiMe}_3}$ bonds. The natural charges of

Table 1 Computed natural charges for **1c**, **2a** and **8a**

Atom label	Natural charges in 1c (Y)	Natural charges in 2a (Y)	Natural charges in 8a (Y) ^{19b}
Y1	2.054	2.164	2.007
C1	−0.253	−0.260	−0.228
O1	−0.867	−0.901	−0.622(imino N)
O1A	−0.867	−0.901	−0.819(carboryne C)
N2A	−0.662	−0.681	−0.816(carboryne C)
N3	−0.654	−0.667	—
O2	−0.636	−0.665	—
C34 or C36	−1.711(C34 in 1c)	−1.716(C36 in 2a)	—

the indol-2-yl carbon atoms in the complexes **1c**, **2a** and **8a** are also smaller than those of the sp^2 carbanion (natural charge of -0.58) bonding with lutetium ion in the pentamethylcyclopentadienyl supported lutetacyclopentadiene, which displayed nucleophilic property according to the DFT calculations and experimental results.³⁵ The natural charges of the indol-2-yl carbon atoms in complexes **1c**, **2a** and **8a** are comparable to those in five-membered organometallic carbenes (ranging from -0.17 to -0.29 for different metals), which exhibit ambiphilic reactivity as indicated by the high values of protons and hydride affinities based on DFT calculations,³⁶ while the resonances for the indol-2-yl carbon atoms (see above) of these complexes can be compared with the resonances (~ 190 – 210 ppm) of the carbonyl carbon atoms of the ketones and aldehydes, which were generally accepted as electrophiles, demonstrating the electrophilic character of the indol-2-yl carbon atoms. Taken together, the indol-2-yl carbon atoms in these complexes can be described as ambiphilic carbon atoms.

Selective reactivity of the RE-C_{2-ind} bond towards organic compounds containing electrophilic carbon or polar N=N double bond. Unusual [2 + 2] cyclometallation and [3 + 3] annulation

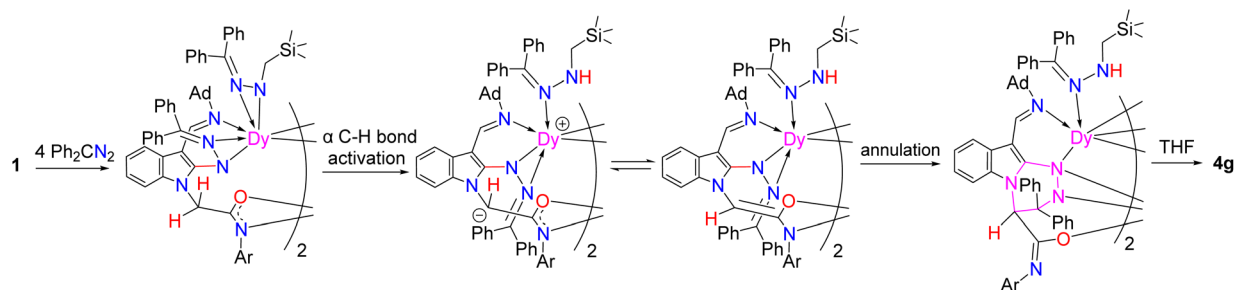

DFT calculations reveal that the natural charge of the indol-2-yl carbon of the complex **1c** is -0.25 (Table 1) and the natural charges of the carbon atoms of the alkyls ($-\text{CH}_2\text{SiMe}_3$) connected to the metal center are around -1.71 , implying that these different RE-C bonds (RE-C_{carbene} and RE-C_{CH₂SiMe₃}) may show different reactivities towards small organic molecules. To this end, the above-synthesized complexes **1** were subjected to reactions with a range of electrophiles (Scheme 4). Complexes

4a–4d (Fig. S66–S69 in the ESI†) were crystallized from different solvents when 0.5 equiv. of complexes **1** were treated with carbodiimides or an aldimine. To our surprise, the RE-C_{carbene} bonds selectively reacted with these electrophiles to generate novel [2 + 2] cyclometallation complexes **4a–4d**, in which the indol-2-yl carbon bonds with the central metal ions in η^1 mode (RE-C_{2-ind} bond lengths: 2.803(4) Å in **4a**, 3.050(3) Å in **4b**, 3.062(3) Å in **4c**, 2.833(5) Å in **4d**, Scheme 4) due to the π -electron moving towards indol-2-yl carbon atoms after the reaction. In contrast, the RE-C_{CH₂SiMe₃} bonds of the complexes **1**, which have the more nucleophilic carbon atoms as demonstrated by DFT calculations, did not react with the corresponding substrates, but reacted with the α C-H bond of the amidate to produce a novel amido-functionalized enolate functionality chelated with the central metal ions in μ - η^1 : η^2 mode (complexes **4a–4d** in Scheme 4). These results are completely different from those of previous studies on the reactivities of rare-earth metal alkyls with carbodiimides and imine, which only produced the carbodiimides or imine insertion products with amidinate or amido being bonded with central metal ions in η^2 or σ bond ways.³⁷

When complexes **1b** and **1e** were reacted with 4 equiv. of diphenyldiazomethane (Ph_2CN_2) at room temperature in THF for 0.5 h, complexes **4e** and **4f** were isolated (Fig. S70 and S71 in the ESI†). While treatment of **1b** with 4 equiv. of diphenyldiazomethane in THF overnight or standing the THF solution of **4e** overnight generated the product **4g** (Fig. S72 in the ESI†) via a rare formal [3 + 3] annulation (Schemes 3, 5 and Fig. 2). The formation of complex **4g** might involve a sequence of insertion of polar N=N bonds of the Ph_2CN_2 into RE-C_{carbene} and RE-C_{alkyl} bonds to afford **4e**, activation of the α C-H bond of the

Scheme 4 The reactions of complexes **1** with electrophiles.

Scheme 5 A tentative pathway to complex 4g.

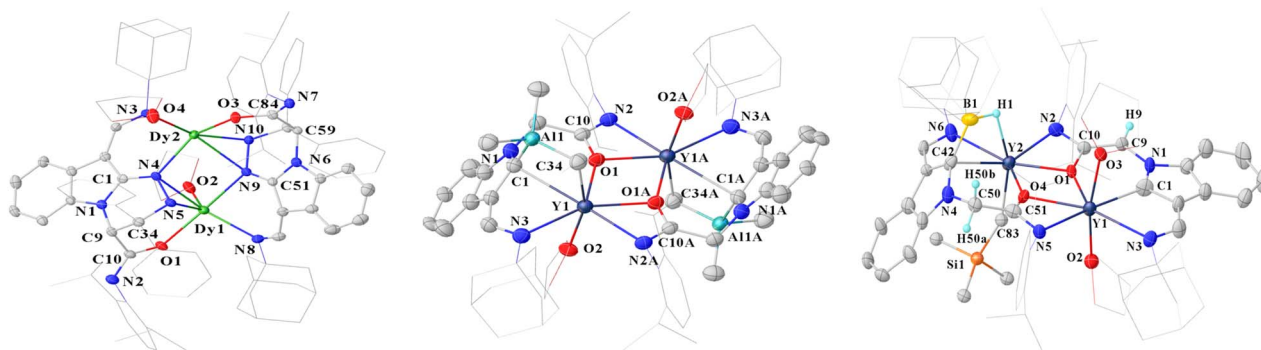

Fig. 2 Molecular structure of 4g (left), 5c (middle) and 5e (right) with the thermal ellipsoid at 30% probability level. All hydrogen atoms were omitted and the diisopropylphenyl (Dipp) group was drawn in wireframe style for clarity. Selected bond lengths (Å) and selected bond angles (deg) can be read in the ESI.†

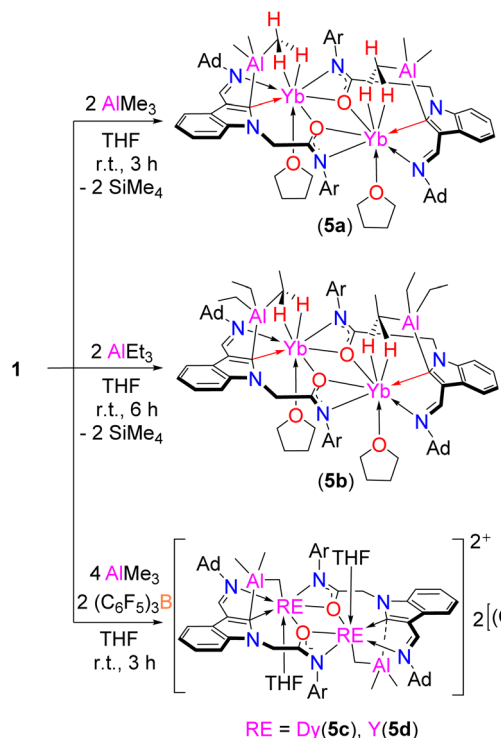

amidate by the anionic $[\text{PhC}=\text{NNCH}_2\text{SiMe}_3]^-$ to produce the amido-functionalized enolate and ring closure with $\text{C}=\text{N}$ bond. The final step is accompanied by transformation of the amidate functionality into an imine functionalized alkoxide type motif.

Selective reactivity of complexes 1 with Lewis acids

To further probe the selective reactivity of the $\text{RE}-\text{C}_{\text{carbene}}$ bonds of complexes 1 towards electrophiles, we then tested their reactions with Lewis acidic compounds such as aluminum alkyls and 9-BBN (9-borabicyclo[3.3.1]nonane). It is interesting to find that the $\text{RE}-\text{C}_{\text{carbene}}$ bonds instead of the $\text{RE}-\text{C}_{\text{CH}_2\text{SiMe}_3}$ bonds, whose carbon has larger natural charge, of complex 1e selectively reacted with the aluminum alkyls AlMe_3 and AlEt_3 to generate novel complexes 5a and 5b (Scheme 6, Fig. S73 and S74 in the ESI†). These complexes bear indol-2- Al_{alkyl} motifs with two sp^3 C–H bonds being σ donated to the ytterbium center, which is reduced to ytterbium(II) from ytterbium(III). Such a reduction is believed to proceed *via* the homolysis of the $\text{Yb}-\text{C}_{\text{CH}_2\text{SiMe}_3}$ bond^{11g,38} due to its lower redox couple ($-1.15 \text{ E}_{295/\text{V}}$) of $\text{Yb}^{3+}/\text{Yb}^{2+}$, which is supported by the identification of the coupling product $\text{Me}_3\text{SiCH}_2-\text{CH}_2\text{SiMe}_3$ ($m/z = 174.126$) from the reaction mixture. The reduction of ytterbium(III) to ytterbium(II) by the aluminum alkyls is occasionally proposed in the polymerization of olefins with mixed ytterbium complexes and aluminum alkyl catalytic systems to explain their poor catalytic activity compared with other rare-earth metal catalysts.^{11d,f,39} However, the proposed ytterbium(II) intermediate has seldom

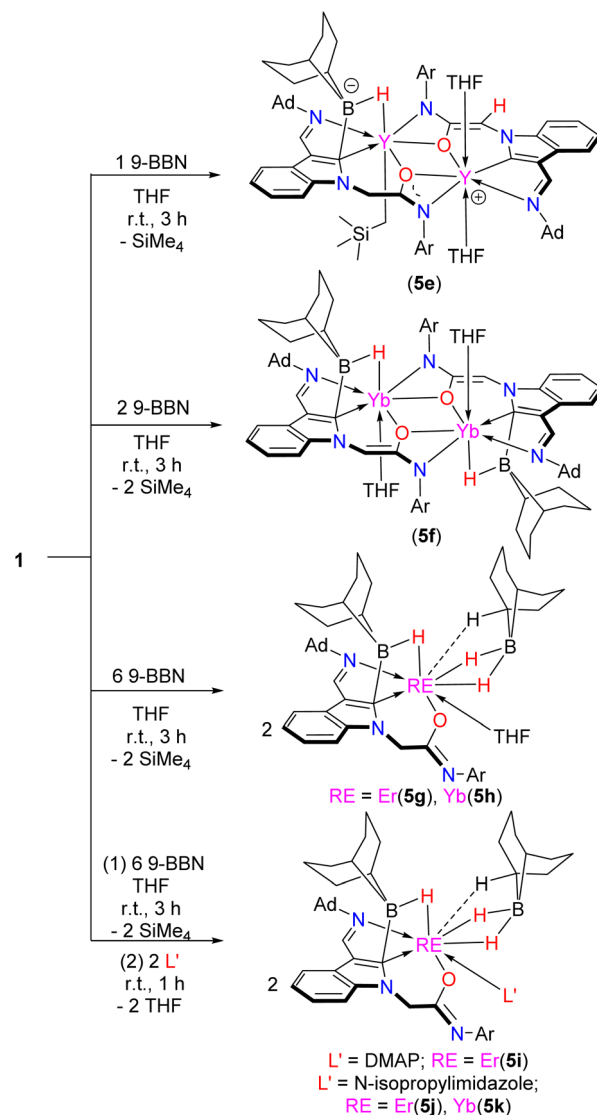

been isolated and characterized. It is surprising to find that either the AlMe_3 or the AlEt_3 exists on the same side to the ytterbium metal in the solid state of the complexes 5a and 5b. Furthermore, the distances of 2.718(8) Å in 5a, and 2.733(4) Å in 5b of the sp^3 C–H interaction with the Yb metal are significantly shorter than that of 2.86 Å found in $\text{Sm}^{\text{II}}-\text{Me}$ interaction in the bis(Me_3Si -fluorene- AlMe_3)Sm complex,⁴⁰ indicating strong σ donation in complexes 5a and 5b. This reactivity pattern is different from the reactions of $\text{L'/Ln}(\text{CH}_2\text{C}_6\text{H}_4\text{NMe}_2\text{-}o)_2$ ($\text{L}' = (\text{PhCH}_2)_2\text{NC}(\text{NC}_6\text{H}_3\text{'Pr}_2\text{-}2,6)_2$) with AlMe_3 or AlEt_3 producing the methyl bridged rare-earth metal–aluminum mixed metal complexes⁴¹ or the ethylene and ethyne complexes.⁴² The $\text{Al}-\text{C}_{2\text{-ind}}$ bond length (2.071(9) Å in 5a, and 2.086(5) in 5b) is within the expected range compared with $\text{Al}-\text{C}_{\text{fluorenyl}}$ (2.101(7) Å).⁴⁰ The average $\text{Yb}^{\text{II}}-\text{C}_{(\text{CH}_3)}$ bond length of 2.711 Å in 7-coordinate 5b is longer than that found in 6-coordinate $\text{Yb}^{\text{II}}\text{Al}_2\text{Et}_8(\text{THF})_2$ (2.633(2) Å),⁴³ which may be due to an electrostatic interaction.

When the rare-earth metal complexes 1b and 1c with the central metal having higher redox potential in comparison with $\text{Yb}^{3+}/\text{Yb}^{2+}$ were treated sequentially with AlMe_3 and $(\text{C}_6\text{F}_5)_3\text{B}$, the cationic rare-earth metal complexes 5c and 5d were isolated from a mixed solution of *n*-hexane and chlorobenzene (Scheme 5, Fig. S75 and S76 in the ESI†). In this process, the $\text{RE}-\text{C}_{\text{carbene}}$ bond selectively reacts with AlMe_3 to deliver the indol-2-yl carbon connected aluminum intermediate, followed by activation of the C–H bond of the AlMe_3 to generate the rare hetero-rare-earth metal–aluminum four-membered metallacycles 5c

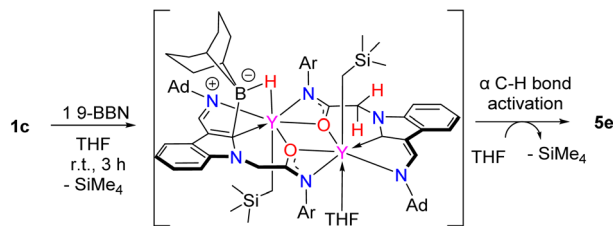

Scheme 6 The reactions of complexes 1 with AlR_3 .

and **5d**. The RE–C(CH₃) bond lengths of 2.353(6) Å in **5c** and 2.356(5) Å in **5d** are comparable to the σ bond length of the Y–C(CH₃)SiMe₃ in **1c**, and the Al–C(CH₃) bond lengths of 1.811(6) Å in **5c** and 1.809(5) Å in **5d** are shorter than that of 1.986(19) Å in **5a**. This reactivity pattern is different from those of the reactions of $\text{L'/Ln}(\text{CH}_2\text{C}_6\text{H}_4\text{NMe}_2\text{-}o)_2$ ($\text{L}' = (\text{PhCH}_2)_2\text{NC}(\text{NC}_6\text{H}_3^i\text{Pr}_2\text{-}2,6)_2$) with AlMe_3 producing the carbyne complex $[(\text{PhCH}_2)_2\text{NC}(\text{NC}_6\text{H}_3^i\text{Pr}_2\text{-}2,6)_2]_2\text{Y}_2(\mu_2\text{-Me})(\text{AlMe}_3)_2(\mu_4\text{-CH})$ and alkyl abstraction product $\text{AlMe}_2(\text{CH}_2\text{C}_6\text{H}_4\text{NMe}_2\text{-}o)$ upon allowing the reaction mixture to stand for 7 days or running the reaction at 60 °C for 18 h.⁴¹ In the present case, one methyl group was transferred to $(\text{C}_6\text{F}_5)_3\text{B}$ to produce the anionic $[(\text{C}_6\text{F}_5)_3\text{BMe}]^-$ part of the complexes, which are also different from the result of the reaction of $[(\text{C}_5\text{Me}_5)\text{La}(\text{AlMe}_4)_2]$ with $(\text{C}_6\text{F}_5)_3\text{B}$, which afforded a $\text{CH}_3/\text{C}_6\text{F}_5$ exchange product $\{[(\text{C}_5\text{Me}_5)\text{La}\{\mu\text{-Me}\}_2\text{AlMe}(\text{C}_6\text{F}_5)]\}[\text{Me}_2\text{Al}(\text{C}_6\text{F}_5)_2]_2$.⁴⁴ The present results are also different from those of the reactions of aluminum alkyls with $\text{B}(\text{C}_6\text{F}_5)_3$ in ether solvent producing the borate $[\text{Me}_2\text{Al}(\text{THF})_2]^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$,⁴⁵ indicating electronic and steric effects of the ligands on the reactivity patterns.

Encouraged by the above results, the reactivity of complexes **1** with Lewis acidic 9-BBN has been investigated. A rare nonsymmetric dinuclear yttrium complex **5e** (Schemes 6 and 7, Fig. 2 and S77 in the ESI†) was obtained when complex **1c** was treated with 1 equiv. of 9-BBN at room temperature in THF. X-ray analysis reveals that complex **5e** is composed of a rare Y–C_{2-ind}–B–H four-membered bora-metallacycle with the indol-2-yl carbon bonding to the metal in the η^1 way. The formation of **5e** might involve selective reaction of the Y–C_{carbene} bond with 9-BBN, while the Y–CH₂SiMe₃ bond of which the carbon has

Scheme 7 The reactions of complexes **1** with 9-BBN.

larger natural charge remains intact. Complex **5e** contains a unique multi-chelate amidate pincer ligand bearing a four-membered bora-metallacycle with the indol-2-yl carbon bonding to the metal centre in the η^1 way in one part, and a multi-chelate amido-functionalized enolate pincer ligand in the other part (Schemes 7 and 8). The Y(2)–C(42)_{ind} bond length (2.741(9) Å) is significantly longer than Y(1)–C(1)_{2-ind} (2.381(10) Å). This suggests that the RE–C(42)_{ind} bond might have transformed from the σ bond into the π bond (η^1) way due to the electron-deficient bora functionality to make the π -electron of the ligand move towards the indol-2-yl carbon (Scheme 1). The Y–H bond length (2.3817(11) Å) was slightly long with those of the Sc–H (borate bridged) (Sc–H = 2.01(3) Å and 2.11(2) Å) when the ionic radii differences were taken into account.⁴⁶ The reaction of complex **1c** with 2 equiv. of 9-BBN in THF leads to the isolation of the central symmetric dinuclear complex **5f** bearing a four-membered bora-metallacycle with the indol-2-yl carbon being η^1 bonded (Yb–C_{2-ind} bond length 2.650(7) Å) to

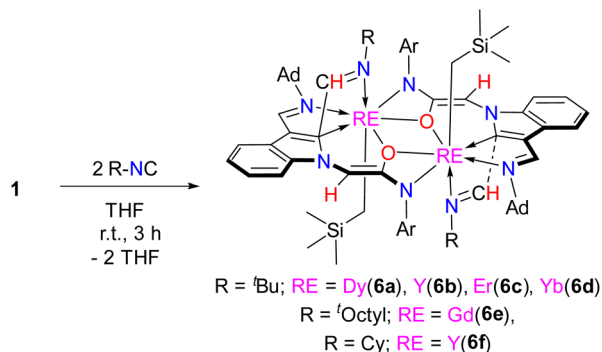

Scheme 8 The formation process of complex 5e.

the metal centres (Scheme 7 and Fig. S78 in the ESI†). The formation of **5f** is believed to go through selective reaction of the Yb–C_{2-ind} bond with 9-BBN to afford the 2-borate indolyl, and the Yb–CH₂SiMe₃ bond activates the α C–H of the amidate group to generate the multi-chelate amido-functionalized enolate 2-borate indol-2-yl ligated dinuclear complex. It is noted that while the four-membered bora-metallacycle has been proposed as an intermediate in the metathesis reactions of the RE–C bond with hydroborate or 9-BBN in the catalytic hydroboration of unsaturated compounds,⁴⁷ to date, structural information about this kind of four-membered ring is rare.

Interestingly, when complexes **1** were treated with excess 9-BBN (6 equiv.) in THF, the THF coordinated mononuclear 2-borate indolyl supported and 9-BBN bridged rare-earth metal hydrides **5g** and **5h** were isolated (Scheme 7 and Fig. S79–S80 in

the ESI†). Stepwise reactions of complexes **1** with excess 9-BBN in THF followed by treatment with donor molecules such as 4-*N,N*-dimethylaminopyridine (DMAP) or *N*-isopropylimidazole (IPIMD) provide DMAP- and IPIMD-coordinated complexes **5i–5k** (Scheme 7 and Fig. S81–S83 in the ESI†). Similar to the formation of complexes **5e** and **5f**, the RE–C_{carbene} bond selectively reacted with 9-BBN first, and then the RE–C_{alkyl} bond reacted with another equivalent of 9-BBN to split the dinuclear complexes into mononuclear ones. An electrostatic C–H interaction (RE–H bond distances 1.976(13) Å to 2.439(18) Å) of the 9-BBN with the rare-earth metal center was found. It is interesting to find that the amidate transforms into the imino-functionalized alkoxide form. This prevents the α C–H of the original amidate from being activated by either the RE–CH₂–SiMe₃ or the newly generated RE–H bonds to generate the amido-functionalized enolate, which is different from the formation of **5e** and **5f**. The indol-2-yl carbon bonds with the central metal ion in the η^1 way due to the electron-deficient bora functionality to make the π -electron of the ligand move towards the carbon. The RE–H bond distances found in **5g** and **5h** (Scheme 7) can be compared to those found in the divalent yttrium and europium 9-BBN complexes, (THF)₄Yb[(μ -H)₂BC₈H₁₄]₂, and (THF)₄Eu[(μ -H)₂BC₈H₁₄]₂,^{48a} the trivalent yttrium tetrahydroborate, (MeOCH₂CH₂C₅H₄)₂Y[(μ -H)₂BH₂]₂,^{48b} and (C₅Me₅)₂Y[(μ -H)₂BC₈H₁₄].^{48c} It is noted that the α C–H activation has not been found in the formation of **5i–5k** with the addition of 4-*N,N*-dimethylaminopyridine (DMAP) or *N*-isopropylimidazole (IPIMD), which is different from the previous reports.^{11g}

Scheme 9 The reactions of complexes **1** with isonitriles.

Selective reactions of the complexes with isonitriles. Unique selectivity and ligand effects on the reactivity patterns

The above results of reactions of the synthesized complexes with electrophiles prompted us to investigate the reactivity of these complexes towards nucleophiles such as isonitriles. It is unexpectedly found that the *tert*-butylisonitrile (*t*BuNC, 2 equiv.) is selectively reacted with carbene carbon atoms (indol-2-yl carbon atoms) of the complexes **1** in THF at ambient temperature, complexes **6a–6d** are generated in good yields, and the highly polarized RE–C_{CH₂SiMe₃} bonds remain intact (Scheme 9, Fig. 3 and Fig. S84–S87 in the ESI†). X-ray crystallography

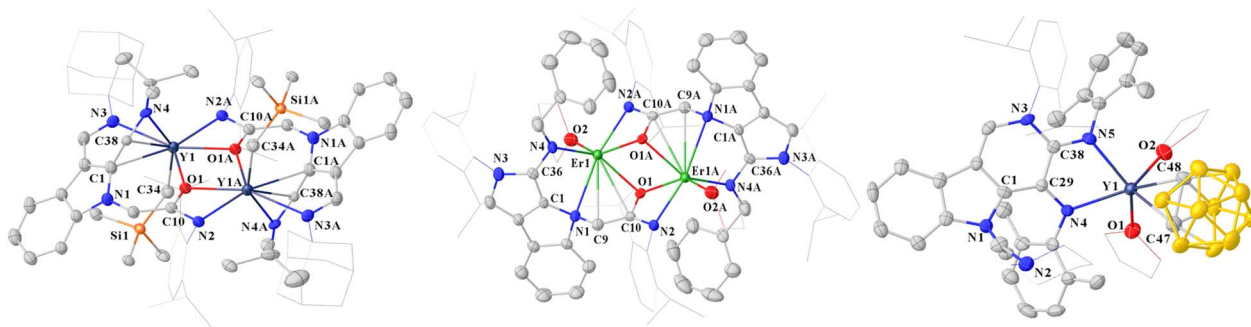

Fig. 3 Molecular structure of **6b** (left), **7d** (middle) and **9a** (right) with the thermal ellipsoid at 30% probability level. All hydrogen atoms were omitted and the diisopropylphenyl (Dipp) group was drawn in wireframe style for clarity. Selected bond lengths (Å) and selected bond angles (deg) can be read in the ESI.†

confirms that complexes **6a–6d** contain the aza-metallacyclobutene motifs with the Y–C_{2-ind} distance of 2.757(6) Å, C_{2-ind}–C_{imino} bond length of 1.510(10) Å, and Y–N4 bond length of 2.459(6) Å. The N4–C38 distance of 1.385(10) Å reveals a C=N double bond character. Complexes **6a–6d** cannot undergo further insertion reaction or C–C coupling in the presence of an excess of ^tBuNC (>2 equiv.) under the reaction conditions. When other isocyanides such as *tert*-octylisocyanide and cyclohexylisocyanide were used, the corresponding rare-earth metal complexes **6e** and **6f** (Scheme 9, Fig. S88 and S89 in the ESI†) containing the aza-metallacyclobutene moiety were also isolated, and the RE–C_{CH₂SiMe₃} bonds remained unreacted. This reactivity pattern is consistent with the electrophilic nature of the indol-2-yl carbon as revealed by DFT calculations (Table 1). However, aryl isocyanides seem incompatible in this reaction system in that the reaction of 2,6-dimethylphenylisocyanide (XylNC) with complex **1f** gave an unidentifiable mixture.

It is proposed that the formation of complexes **6** involves coordination of isocyanide to the electrophilic metal centre with the release of THF to afford the intermediate ^{Ad}Y1, which then undergoes 1,1-migratory insertion to the electrophilic indol-2-yl

carbene carbon^{18,19a,c} to produce the intermediate ^{Ad}Y2. The Y–C_{2-ind} bond cleavage occurs with intramolecular redox to afford the intermediate ^{Ad}Y3, which then abstracts the proton of the α C–H of the amidate group to deliver the final product (Scheme S30 in the ESI†). This reactivity pattern is different from the known reaction of a free singlet carbene with an isocyanide to generate a ketenimine.⁴⁹ To the best of our knowledge, the selectivity and reactivity found in the above reactions have so far been unreported.⁵⁰ It is noteworthy that the Y–N4 bonds (2.459(6) Å) in **6b** are significantly longer than those in the [(C₅H₅)Y(μ,η²-HC=NCMe₃)]₂ dimer (2.325(4) Å),^{51a} and in the Cp*₂Zr(iminoacyl)CH₃(Cp* = C₁₀H₁₅) monomer (2.368(2) Å)^{51b} respectively, due to different coordination numbers and/or different central metal ions.

Next, taking the reaction of **1c** with ^tBuNC to produce **6b** as an example, DFT calculations were performed to investigate the possible reaction pathways and reasonable energy profiles (see the ESI† for details). The results showed that the total reaction was exergonic –42.4 kcal mol^{–1}, and the reaction barriers were consistent with room temperature conditions. The formation of complex **6b** might proceed *via* a stepwise process at each metal

Scheme 10 Computed enthalpy profile for the formation of **6b** from **1c**. The enthalpy is given in kcal mol^{–1}.

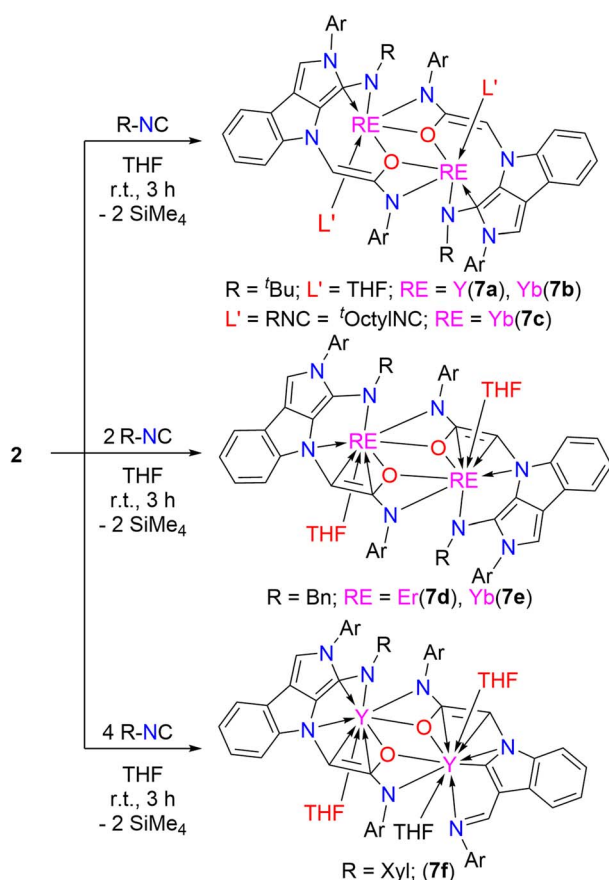

centre to accomplish the formation of the aza-metallacyclobutene moiety. After coordination of the $^t\text{BuNC}$, the 1,1- $^t\text{BuNC}$ migratory insertion accompanied by $\text{Y}-\text{C}_{2\text{-ind}}$ cleavage leads to the reduction of isonitrile $\text{C}\equiv\text{N}$ triple bond to the imido anion (intramolecular redox). This process is preferred to the 1,1- CH_2SiMe_3 migratory insertion with a formation of relatively stable intermediate $^{\text{Ad}}\text{B}$ ($-6.3 \text{ kcal mol}^{-1}$) vs. $^{\text{Ad}}\text{B}'$ ($8.4 \text{ kcal mol}^{-1}$). The intermediate $^{\text{Ad}}\text{B}$ transforms into the intermediate $^{\text{Ad}}\text{C}$ ($5.6 \text{ kcal mol}^{-1}$), which then undergoes another 1,1- $^t\text{BuNC}$ migratory insertion accompanied by $\text{Y}-\text{C}_{2\text{-ind}}$ cleavage leading to reduction of isonitrile $\text{C}\equiv\text{N}$ triple bond to generate the intermediate $^{\text{Ad}}\text{D}$ ($-12.9 \text{ kcal mol}^{-1}$). The process of abstraction of the α C-H of the amidate group to form intermediate $^{\text{Ad}}\text{E}$ ($-27.0 \text{ kcal mol}^{-1}$) is favourable to the cycloaddition of the imino nitrogen of the ligand to the ketenimine carbon. The $^{\text{Ad}}\text{E}$ then abstracts another proton of the α C-H of the amidate group to deliver the final product **6b** ($-42.4 \text{ kcal mol}^{-1}$) (Scheme 10).

To get more direct information of the substituent effects on the reactivity, we then investigated the reactivity of different complexes towards various isonitriles. It is surprising to find that when complexes **2** bearing the ligand with a diisopropylphenyl substituent instead of the adamantyl substituent in **1** were treated with different isonitriles ($\text{R}-\text{NC}$, $\text{R} = ^t\text{Bu}$, $^t\text{Octyl}$, Bn , Xyl) under the otherwise same conditions, novel $[4 + 1]$ annulation products of 1-amido-functionalized enolate indolo-fused

2-amido-pyrrolyl complexes **7** (Scheme 11, Fig. 3, and S90–S95 in the ESI†) were isolated with moderate yields. In this process, the carbene carbon atoms (indol-2-yl carbon atoms) have displayed unexpected selective reactivity towards the nucleophilic isonitriles, which is completely different from that found in reactions of **1** with isonitriles. This suggests that the substituents on the ligand, which may lead to changes in both steric hindrance and electronic nature of complexes **1** and **2** (different natural charges of the central metal ion and the bonding atoms, see Table 1), have profound effects on the reaction pathways. The current results with isonitriles are also completely different from those in recently reported reactions of rare-earth metal monoalkyl complexes with isonitriles, which provided multi-substituted β -diketiminato or multi-substituted imidazolyl complexes.⁵² On the basis of the DFT calculation results, it is proposed that coordination of the isonitrile to complex **7a** (as an example) gives the intermediate $^{\text{Dipp}}\text{Y1}$, which then undergoes 1,1-migratory insertion to generate $^{\text{Dipp}}\text{Y2}$. Isomerization of $^{\text{Dipp}}\text{Y2}$ gives the ketenimine⁴⁹ intermediate $^{\text{Dipp}}\text{Y3}$. Then the amido nitrogen of the ligand attacks the central carbon of the ketenimine to finish the cyclization to form the $[4 + 1]$ annulation products of indolo-fused 2-amido pyrrolyl fragments $^{\text{Dipp}}\text{Y4}$. The $\text{RE}-\text{C}_{\text{CH}_2\text{SiMe}_3}$ bonds activate the α C-H bonds of the amidate to deliver the final 1-amido functionalized enolate chelate indolo-fused 2-amido-pyrrolyl ligated complexes (Schemes 12 and S31 in the ESI†).

It should be noted that when complexes **2** were directly treated with excess *tert*-octylisonitrile ($^t\text{OctylNC}$) (4 equiv.), the C-C coupling or C-N coupling products through insertion of $\text{RN}\equiv\text{C}$ to the $\text{RE}-\text{C}_{\text{CH}_2\text{SiMe}_3}$ bonds or through insertion of $\text{RN}\equiv\text{C}$ to the $\text{RE}-\text{N}$ bonds as those reported in the literature were not obtained,^{51,53} while the $^t\text{OctylNC}$ coordinated complex **7c** was isolated instead. Also of note is that the original bonding modes of the ligand change from $\eta^1:\eta^1:(\mu-\eta^1:\eta^2)$ to $\sigma:\eta^1:(\mu-\eta^1:\eta^2)$ after the cyclization, that is, the newly generated amido-functionalized pyrrolyls bond with the central metal in $\sigma:\eta^1$ ($\text{RE}-\text{C}_{2\text{-pyr}}$: 2.669(13) Å to 2.793(13) Å) and the amido-functionalized enolates bond with the central metal in $\mu-\eta^1:\eta^2$ ways in complexes **7a–7c**. When the substituents of isonitriles are benzyl or xyl (**7d–7f**), the reactions are compatible with these substrates, which are different from that of reaction of **1** with the xyl substituted isonitrile. It is found that the $\text{C}=\text{C}$ double bonds of the newly formed amido-functionalized enolates in **7d–7f** have bonding interaction with the central metal as indicated by the $\text{RE}-\text{C}$ bond distances of 2.685(7) Å to 2.715(5) Å.

In order to further understand the reaction process, the formation of complex **7a** from the reaction of complex **2a** with $^t\text{BuNC}$ was calculated by DFT (Scheme 12, see the ESI† for details). It reveals that the replacement of THF by $^t\text{BuNC}$, followed by a stepwise 1,1-migratory insertion on each metal centre to generate the intermediate $^{\text{Dipp}}\text{D}$ are parallel to those for the formation of **6b** as discussed above. The transformation of $^{\text{Dipp}}\text{D}$ into the indolo-fused amido-functionalized pyrrolyl motif ($^{\text{Dipp}}\text{E}$) is favoured over the transformation of $^{\text{Dipp}}\text{D}$ into aza-metallacyclobutene ($^{\text{Dipp}}\text{E}'$) ($4.0 \text{ kcal mol}^{-1}$ vs. $4.6 \text{ kcal mol}^{-1}$). The intermediate $^{\text{Dipp}}\text{E}$ then undergoes a stepwise C-H activation with the $\text{RE}-\text{CH}_2\text{SiMe}_3$ bond followed by

Scheme 11 The reactions of complexes **2** with isonitriles.

coordination of THF to deliver the final products. These results suggest that the substituents on the ligands have influence on the electronic properties of the complexes and stability of the transition state and intermediates, thereby determining the reaction pathways of the complexes.

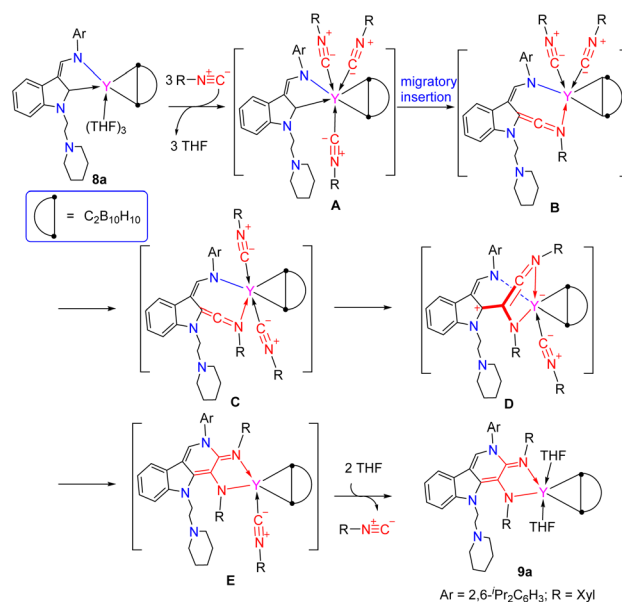

To prove the above results that ligands have profound influences on the reactivity patterns of rare-earth metal

complexes with isocyanides, we then studied the reactivity of the rare-earth metal complexes bearing both electrophilic carbene and strongly polarized three-membered metallacycles with isocyanide. Treatment of the carboryne-based strongly polarized metallacyclopentane ($\kappa^2\text{-L}^1$)RE($\eta^2\text{-C}_2\text{B}_{10}\text{H}_{10}$)(THF)₃ [**L**¹ = 1-(2-*N*-C₅H₁₀NCH₂CH₂)-3-(2,6-*i*-Pr₂C₆H₃N=CH)-C₈H₄N, RE = Y(**8a**), Er(**8b**), Lu(**8c**)]^{19b} with 3 equiv. of XylNC afforded the

unprecedented selective reaction complexes **9** bearing an α,β -di(2,6-dimethylphenyl)amido- γ -(*N*-2,6-diisopropylphenyl)carboline (or indolo-fused multi-functionalized pyridine)-based ligand (Scheme 13, Fig. 3 and S96–S98 in the ESI†). It is surprising to find that the highly strained and polarized metallacyclopropane moiety remains intact in the process, while the formation of the indolo-fused multi-functionalized pyridine moiety involves the coupling of the electrophilic carbene carbon and the nucleophilic nitrogen atom of the ligand (1-(2- C_5H_{10} -NCH₂CH₂)-3-(2,6- 1Pr_2C_6H_3NCH)- C_8H_4N)-2-yl with two molecules of 2,6-dimethylphenylisocyanide *via* an unexpected aza-[4 + 1 + 1] annulation, which is obviously different from the reactivity of the zirconium–carboryne complex with isocyanide to produce the zirconium complex having the [$^tBuN=C=C$][−] ketenimine moiety functionalized carborane anion through the insertion of isocyanide into the Zr–C_{cage} bond accompanied by the Zr–C_{cage} bond cleavage.^{19b} The result is also different from those of the reactions of lutetium metallacyclopropene with phenylisocyanide followed by treatment with 2,6-dimethylphenylisocyanide to produce the functionalized pyrrolyl moiety complex.³⁵ This result is also obviously different from the reactions of the rare-earth metal complexes **1** and **2** with isocyanides to generate the multi-substituted aza-[4 + 1] annulation and the [2 + 2] cyclometallation products as discussed above. These differences in reactivity patterns towards isocyanides may probably be due to ligands, central metal ions, coordination environments around the central metals, and electrophilic property of the indol-2-yl carbon atoms (comparison of the natural charge of the carbon about −0.253 in **1c** and −0.260 in **2a** with −0.228 in the corresponding carboryne-based yttrium metallacycle **8a**, see Table 1). It is found that the average lengths of the RE–C_{cage} bond in **9** are shorter than those of the corresponding rare-earth metallacyclopropane complexes (κ^2 -L¹)RE(η^2 -C₂B₁₀H₁₀)(THF)₃, which may be attributed to the difference in ionic radii between the different coordination numbers in complexes (κ^2 -L¹)RE(η^2 -C₂B₁₀H₁₀)(THF)₃. It is noted that the coupling of the imino nitrogen atom with unsaturated substrates is only involved in the aza-Diels–Alder reactions, where the imine nitrogen generally bears electron-withdrawing groups.

DFT calculations of complexes (κ^2 -L¹)RE(η^2 -C₂B₁₀H₁₀)(THF)₃ (RE = Y, Lu) showed that the natural charges of the indol-2-yl carbon are −0.228 in yttrium and −0.213 in lutetium complexes,^{19b} which are comparable with those found in complexes **1** and **2**, indicating that the indol-2-yl carbon is an electrophilic carbon because the corresponding p-orbital lacks electrons. These results are parallel to our previous findings of the indol-2-yl carbon which exhibited electrophilic property to make the 1,1-alkyl and 1,1-H (or D) migratory insertion possible,^{18,19a} and findings of unique reactivity patterns towards pyridine derivatives.^{19c} Based on these results, the formation of the γ -carboline-based α,β -diamido moiety functionalized complexes could be described as follows: complex (κ^2 -L¹)Y(η^2 -C₂B₁₀H₁₀)(THF)₃ was transformed into the intermediate **A** through ligand substitution, in which the indol-2-yl carbon is more electrophilic than that in (κ^2 -L¹)Y(η^2 -C₂B₁₀H₁₀)(THF)₃ (natural charge: −0.132 in **A** vs. −0.228 in (κ^2 -L¹)Y(η^2 -C₂B₁₀H₁₀)(THF)₃, Table S29 in the

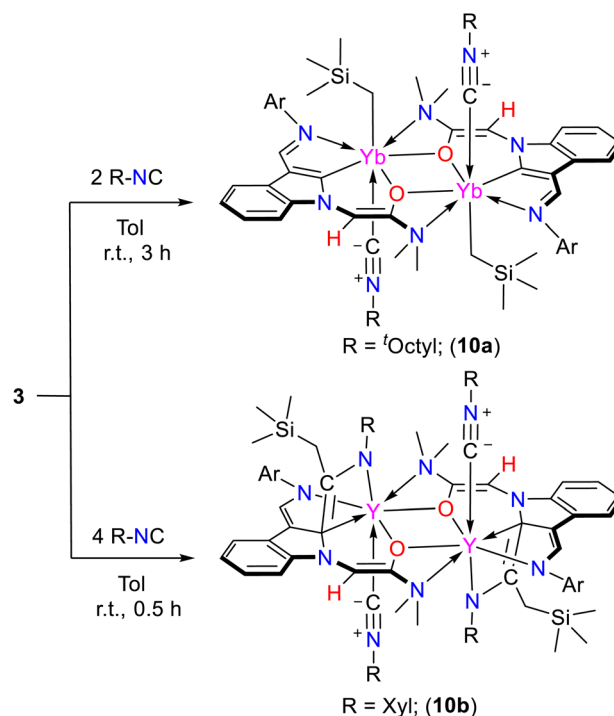

Scheme 14 A possible reaction pathway for the reaction of indolyl rare-earth carboryne-based metallacyclopropanes with XylINC.

ESI†). The migratory insertion of the polarized coordinated isocyanide to the enamido-functionalized carbene with Y–C_{carbene} bond cleavage produced the ketenimine intermediate **B**, which has been found in the reaction of free singlet carbene with isocyanide,⁴⁹ and is parallel to the above results of reactions of complexes **2** with isocyanides delivering intermediate ^{dipp}**D**. Then **B** underwent isomerization from *cis*-coordinated isocyanide to *trans*-coordinated isocyanide to give the ketenimine intermediate **C**, which then reacted with the coordinated isocyanide through insertion to afford the ketenimine intermediate **D** of the five-membered metallacycle. The difference in reactivity between the above formed rare-earth metal ketenimine intermediate and the present rare-earth metal ketenimine intermediate in the reactions with isocyanides can be attributed to the existence of the electrophilic carboryne motif, which may make the central carbon of the ketenimine more electrophilic, thereby allowing the coordinated isocyanide to attach to it easily. The amido group of the enamido functionality attached the carbon of the C=N double bond to produce the γ -carboline-based α,β -amidoimino moiety **E**, which then coordinates with two molecules of THF with release of one isocyanide to produce the final product **9a** (Scheme 14).

To gain some insights into the formation of complex **9a** from complex **8a**, the computational studies were carried out at the level of B3PW91 including dispersion corrections (see the ESI† for details). The first step of the reaction is the formation of an yttrium centre with three coordinated isocyanide molecules, which will give a more stable **A** with corresponding indol-2-yl carbon which is more electrophilic (natural charge from −0.228 to −0.132). Two isomers were found (namely **A** and **A'** in Scheme S32 in the ESI†) that would allow two different reactivities. The most stable isomer is **A** which is 4.8 kcal mol^{−1} more stable than **A'**, so that the latter will never be formed, preventing the red

pathway in Scheme S32 in the ESI†. The red pathway, although kinetically accessible (barrier of $18.1 \text{ kcal mol}^{-1}$), is the insertion of isonitrile into the Y–C_{cage} bond, while the black pathway, which is kinetically competitive (within the precision of the computational method) with the red pathway (barrier of $23.3 \text{ kcal mol}^{-1}$), is the insertion into the Y–C_{carbene} bond. Following the intrinsic reaction coordinates for both pathways, it yields complex **B'** and **C** where the latter is more stable than the former by $2.7 \text{ kcal mol}^{-1}$ so that only complex **C** will be observed. This completely ruled out the reaction of isonitrile with the Y–C_{cage} bond. Complex **C** is an amido complex bearing a C=C=N group which is reminiscent of an anionic aza-allyl group. This C=C=N cumulenonic ketenimine system contains a central sp²-hybridized carbon atom that is electron-deficient. Thus, a second molecule of isonitrile undergoes a nucleophilic addition to the central carbon of the ketenimine at TS2 with an associated barrier of $20.8 \text{ kcal mol}^{-1}$. Following the intrinsic reaction coordinate, it yields another stable ketenimine intermediate **D** ($-23.9 \text{ kcal mol}^{-1}$), which readily isomerizes through a ring closure reaction of the nucleophilic addition of the Y–N bond to the central carbon of the ketenimine (TS3). The associated barrier of this last step is $16.4 \text{ kcal mol}^{-1}$ and leads to the stable formation of intermediate **E** ($-64.9 \text{ kcal mol}^{-1}$). The latter exchanges an isonitrile with two THF molecules to yield the experimentally observed complex **9a**. This ligand exchange is very exothermic in line with the crystallization of complex **9a** (Scheme S32 in the ESI†).

Our attempts to isolate the isonitrile coordinated intermediates to prove the coordinative (or nucleophilic) ability of the nitriles in the formation of complexes **6**, **7** and **9** are not successful. Then, the non-THF coordinated complexes **3** bearing the amino-functionalized enolate chelate ligands were synthesized, and their reactivity towards isonitriles was studied. To our delight, the ^tOctylNC coordinated (Yb–C_{NC^tOctyl} bond lengths of $2.656(9) \text{ Å}$) complex **10a** (Scheme 15 and Fig. S99 in the ESI†) was separated in a moderate yield from the reaction of the dinuclear ytterbium complex **3c** with 2 equiv. of ^tOctylNC in toluene at ambient temperature. This result supports the proposed coordination of isonitrile with Lewis acidic rare-earth metal centers and provides insights into the proposed intermediate equivalents ^{Ad}**A**, ^{Dipp}**A** and **A** in the formation of complexes **6**, **7** and **9**. Complex **10a** does not further react with excess ^tOctylNC on either the synthetic or NMR scale, indicating ligand effects on the reactivity. However, when dinuclear complex **3a** was treated with XylNC, complex **10b** (Scheme 15, Fig. 4 and S100 in the ESI†) bearing an aza-metallacyclobutene moiety was isolated. In **10b**, the C=C double bond (C_{2-ind}–C_{isonitrile} = $1.383(6) \text{ Å}$, and C_{isonitrile}–N_{isonitrile} = $1.388(6) \text{ Å}$) is different from the aza-metallacyclobutene having a C=N double bond (C_{2-ind}–C_{isonitrile} = $1.510(10) \text{ Å}$, C_{isonitrile}–N_{isonitrile} = $1.385(10) \text{ Å}$) in the four-membered ring in complexes **6**. It is proposed that the formation of **10b** involves coordination of the isonitrile to the metal centre to give the intermediate **10a**, which then undergoes 1,1-migratory insertion to generate the ketenimine intermediate. The ketenimine inserts into the RE–C_{CH₂–SiMe₃} bonds to deliver the final products, which is also different from that in the formation of **6** (Scheme S33 in the ESI†).

Scheme 15 The reactions of complexes **3** with isonitriles.

This reactivity pattern is different from those in the formation of complexes **6**, **7** and **9** highlighting again the influence of ligands on the reactivity patterns. Thus, four different reactivity patterns were found in the reactions of the synthesized rare-earth metal complexes with isonitriles: (1) replacement of THF of complexes **1** by isonitriles affords the isonitrile coordinated intermediates, which then undergo a stepwise 1,1-isonitrile migratory insertion to the carbene carbon to generate the intermediates having imidoyl anion attached to the indol-2-yl carbon *via* intramolecular redox. The imidoyl anion abstracts proton of the α C–H of the amidate to produce the final complexes **6** containing the aza-metallacyclobutene with a C=N

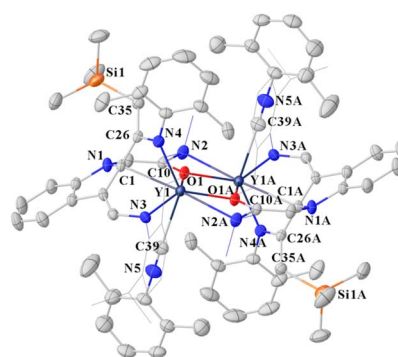

Fig. 4 Molecular structure of **10b** with the thermal ellipsoid at 30% probability level. All hydrogen atoms were omitted and the diisopropylphenyl (Dipp) group was drawn in wireframe style for clarity. Selected bond lengths (Å) and selected bond angles (deg) can be read in the ESI†.

double bond. (2) The stepwise coordination and 1,1-isonitrile migratory insertion with subsequent isomerization with complexes **2** produce the ketenimine intermediate, which then was attached by the amido nitrogen to generate [4 + 1] annulation products of the indolo-fused 2-amido-functionalized pyrrolyl ligated complexes **7**. (3) Coordination of the polarized isonitrile to the metal centre to produce a more electrophilic indol-2-yl carbon followed by 1,1-isonitrile migratory insertion to give the ketenimine intermediate. A second molecule of isonitrile undergoes a nucleophilic addition to the central carbon of the ketenimine yielding another ketenimine intermediate which is attached by the amido nitrogen followed by coordination with two molecules of THF to form the unprecedented aza-[4 + 1 + 1] annulation product **9**. (4) Coordination of the isonitrile to the metal centre followed by 1,1-isonitrile migratory insertion to give the ketenimine intermediate, which then inserts into the RE-C_{CH₂SiMe₃} bond to produce the complexes **10** with aza-metallacyclobutene motifs having a C=C double bond.

Conclusions

In summary, three different types of novel rare-earth metal complexes bearing 1-multi-chelated amidate-3-imino functionalized indol-2-yl pincer ligands (complexes **1** and **2**) or 1-multi-chelated amino-functionalized enolate-3-imino functionalized indol-2-yl pincer ligand (complexes **3**) were synthesized with rationally designed ligands. DFT calculations and experimental results reveal that the indol-2-yl carbon atoms of the ligands in the complexes can be described as ambiphilic carbenes, which display unprecedented selective reactivity towards electrophiles and nucleophiles. The RE-C_{2-ind} bonds (or RE-C_{carbene} bonds) of these complexes exhibit unexpected selective reactivity towards electrophiles like carbodiimides or imine to generate unusual [2 + 2] cyclometallation products of the aza-metallacyclobutane moiety. The reactions of these complexes with diphenyldiazomethane Ph₂CN₂ produce either insertion complexes or a rare complex bearing an indolo-fused six-membered ring *via* [3 + 3] annulation, depending on the amount of Ph₂CN₂. The RE-C_{carbene} bonds also show selective reactivity towards Lewis acidic compounds such as AlR₃ (R = Me, Et) and 9-BBN to produce alumina- or bora-four-membered metallacycles with short RE-H-C interactions. The reactions of the newly synthesized complexes and complexes bearing electrophilic carbene and metallacyclop propane with isonitriles display four types of unique selective reactivity patterns of the carbenes: (1) the replacement of coordinated THF by isonitriles followed by 1,1-isonitrile migratory insertion to the carbene carbon with subsequent intramolecular redox and abstraction of proton of the α C-H of the amidate to generate the formal [2 + 2] cyclometallation products of aza-metallacyclobutene having a C=N double bond; (2) the substitution of THF by isonitriles followed by 1,1-isonitrile migratory insertion to the carbene carbon and isomerization to the ketenimine intermediate, which was then attacked by the nitrogen of the ligands with subsequent α C-H activation by the RE-CH₂SiMe₃ to deliver the novel aza-[4 + 1] annulation products of 1-(amido-

functionalized enolate)-indolo-fused-2-amido-pyrrolyl ligated complexes; (3) coordination of the polarized isonitrile to the metal centre to produce a more electrophilic indol-2-yl carbon followed by 1,1-isonitrile migratory insertion to give the ketenimine intermediate. A second molecule of isonitrile undergoes a nucleophilic addition to the central carbon of the ketenimine yielding another ketenimine intermediate which is attached by amido nitrogen followed by coordination with two molecules of THF to form the unprecedented aza-[4 + 1 + 1] annulation products; (4) the coordination of the isonitrile with subsequent 1,1-isonitrile migratory insertion into the carbene carbon and isomerization to a ketenimine intermediate, which then gets inserted into the RE-C_{CH₂SiMe₃} bond to generate the multi-substituted [2 + 2] cyclometallation products of aza-metallacyclobutene having a C=C double bond. This work provides plenty of insights into the reactivity of rare-earth metal complexes bearing both ambiphilic carbene and nucleophilic carbon atoms, and demonstrates unique selective reactivity patterns of the rare-earth metal ambiphilic carbenes, which may be applicable in understanding and designing new catalytic reactions. Further work in this field is in progress.

Data availability

Experimental procedures, X-ray crystallographic details, NMR spectroscopy data, and computational details are available in the ESI.† CCDC 2258652–2258653, 2386247–2386289, 2258655, 2278784, 2278786 and 2278788 contain the supplementary crystallographic data for this paper.

Author contributions

F. Chai led and performed the synthesis, reactivity study of the amido-functionalized indol-2-yl rare-earth metal complexes and experiments for the characterization of the complexes, and manuscript draft writing. W. Wu led and performed the synthesis, reactivity study of the indol-2-yl rare-earth carbonyne-based metallacyclop propane and experiments for the characterization of the complexes. T. Rajeshkumar performed the DFT calculations and analyse the results under the supervision of L. Maron. Z. Huang, Q. Yuan and Y. Wei assisted in the analysis of experimental data. L. Maron supervised and participated in the discussion on DFT calculation results. S. Wang is responsible for the project design, discussion, manuscript writing, and editing.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

Financial support for this work was provided by the National Natural Science Foundation of China (No. 22031001, U23A2079 and 22301005). The authors are thankful for the grants from the Anhui Province (202305a12020018, GXXT-2021-052) and the Wuhu Science and Technology project (2023jc16). We

appreciate the help of Dongjing Hong (Anhui Normal University) in the crystal data process and structure solution and refinement.
