Recent progress in metal–organic framework/graphene-derived materials for energy storage and conversion: design, preparation, and application

Kaixi Wang,^{ab} Kwun Nam Hui,^{id b} Kwan San Hui,^{id d} Shaojun Peng^{id *c}
and Yuxi Xu^{id *a}

Graphene or chemically modified graphene, because of its high specific surface area and abundant functional groups, provides an ideal template for the controllable growth of metal–organic framework (MOF) particles. The nanocomposite assembled from graphene and MOFs can effectively overcome the limitations of low stability and poor conductivity of MOFs, greatly widening their application in the field of electrochemistry. Furthermore, it can also be utilized as a versatile precursor due to the tunable structure and composition for various derivatives with sophisticated structures, showing their unique advantages and great potential in many applications, especially energy storage and conversion. Therefore, the related studies have been becoming a hot research topic and have achieved great progress. This review summarizes comprehensively the latest methods of synthesizing MOFs/graphene and their derivatives, and their application in energy storage and conversion with a detailed analysis of the structure–property relationship. Additionally, the current challenges and opportunities in this field will be discussed with an outlook also provided.

Introduction

Metal–organic frameworks (MOFs), also known as porous coordination polymers with tunable pore sizes and structures, as well as high specific surface area and pore volume, have been extensively investigated as a new class of inorganic–organic hybrid materials and grown to be an ideal platform for various advanced functional materials and applications. Owing to the easily tunable chemical compositions of the organic linkers and metal nodes (metal ions/clusters), more than 20 000 different MOFs have been designed and synthesized in the past two decades. Their unique structures and properties make them potential candidates in many applications, such as environmental protection,^{1–3} drug delivery,^{4,5} gas adsorption and separation,^{6–9} sensors,^{10–12} catalysis,^{13–15} electrochemical energy storage,^{16–21} etc. Nevertheless, it should be noted that most pristine MOFs still suffer from the intrinsic drawbacks of low structural stability and poor electrical conductivity, which hinder their practical applications, especially in the field of

electrochemical energy storage and conversion.^{22,23} Encouragingly, many efforts have been made to address these issues. Typically, three strategies have been developed, including designing conductive MOFs by using metal ions and organic ligands with loosely bound electrons,²⁴ post-synthetic modification of MOFs by modifying the linker and/or metal node, and adsorption/exchange of guest species,^{25,26} and constructing composites with MOFs and other materials,^{17,27} such as MOF/carbon hybrid materials, including MOF/carbon paper,²⁸ and MOF/carbon nanotubes.²⁹ Among them, the resultant MOF composites have become more prominent due to the synergic effects between the two components.

Graphene, a fascinating two-dimensional (2D) carbon nanosheet with a conjugated hexagonal lattice, has drawn great interest in energy storage and conversion fields due to its huge theoretical surface area, superior electrical conductivity, excellent electrochemical stability, and other unique physical and chemical properties.^{30–34} However, the aggregation and restacking phenomena caused by the strong π – π interaction between graphene layers lead to a great loss of both accessible specific surface area and outstanding single-layer electric properties of graphene, presenting a relatively low electrochemical performance.^{35–37} Assembling graphene and other electrochemical materials to generate a composite has so far been well-accepted to be an effective approach to solve the problem since the introduced component between individual graphene layers can separate them. This composite material is likely to inherit the advantages of the two parent components,

but at the same time eliminate their respective shortcomings, which is conducive to the improvement of overall electrochemical performance.

Based on the above analysis, it is desirable to design MOF/graphene-based composites for enhanced electrochemical application. Graphene or chemically modified graphene, because of its high specific surface area and abundant functional groups, provides an ideal template for the controllable growth of MOF particles. With the assembly of MOFs and graphene, the disadvantages of each component can be circumvented and the advantages imparted. (i) The ultrathin graphene nanosheets are stabilized in the presence of MOFs, which ensures that a large accessible surface and many active sites are exposed. (ii) The limitation of poor conductivity of MOFs is alleviated when coupled with graphene, hence promoting electron transport in the whole electrode. (iii) Wrapping MOFs within graphene endows them with much better structural stability during the rapid electrochemical process, resulting in longer cycle life of electrodes.³⁸ (iv) The hierarchical pore structures generated in the composite offer a perfect space for accessing the electrolyte and reducing the mass transfer resistance, thus boosting the reaction kinetics.^{36,38} In particular, some unexpected effects take place during the preparation and application process of MOF/graphene-based composites. Ultra-small MOFs with an average size below 10 nm grown on graphene oxide (GO) have been achieved as the excess metal ions facilitate the effective deposition of MOFs by electrostatic and coordination interactions and inhibit their overgrowth.³⁹ Moreover, the strong chemical interface between MOF nanocrystals and reduced graphene oxide (rGO) can substantially enhance the adsorption energy and ion transport kinetics for outstanding energy storage performance.⁴⁰ What's more, construction of MOF/graphene nanocomposites with their tunable composition and structures can be easily transformed into single atoms, carbonaceous nanomaterials, metal oxides, sulfides, phosphides, carbides, and nitrides with sophisticated structures,^{39,41–47} showing their unique advantages and great potential in energy storage and conversion, such as supercapacitors,⁴⁸ lithium-ion batteries (LIBs),⁴⁹ lithium-sulfur batteries,^{50–53} sodium-ion batteries, potassium-ion batteries, lithium-oxygen batteries,⁵⁴ CO₂ reduction,^{17,55} oxygen evolution and reduction reactions,^{46,56,57} etc.^{58,59}

Owing to the aforementioned advantages, MOF/graphene-based materials have received enormous attention. The related studies have been increasing in recent years and becoming a hot research topic. Our group have also achieved progress in this research field and thus have a deep understanding of the current research status and challenges.^{38–42,44,45,60–64} Although there are a few reviews about MOF/graphene-based materials and their applications, they do not include the most recent/latest developments of MOF/graphene-based materials in energy-focused applications, or only focus on limited or other aspects (application in environmental remediation, or catalysis).^{2,23,43,65} Different from previous reviews, we will comprehensively summarize the recent advances of MOFs/graphene and their derivatives, and focus on their application in energy storage and conversion (Fig. 1). First, the latest

methods of synthesizing MOFs/graphene and their derivatives will be highlighted. Then, the structure–property relationship and its application in energy storage and conversion will be further elucidated in detail. Finally, the challenges and opportunities in this field will be discussed with an outlook also given. We believe this review will attract broad interest from researchers in the chemistry and materials community and stimulate the further development of MOF/graphene-based functional materials.

Design and preparation of MOF/graphene nanocomposites

In recent years, significant efforts have been made on developing different synthetic strategies for preparing MOF/graphene nanocomposites with various functional components, structures, morphologies, and applications (Table 1). The synthetic strategies of MOF/graphene materials can be generally divided into three types according to the growth and combination of MOFs with graphene: physical mixing, *in situ* growth, and excess metal-ion induced *in situ* growth. No matter which route is used, graphene oxide (GO) is initially used and then reduced to obtain MOF/graphene nanocomposites. It should be pointed out that “graphene” in this review may also refer to GO, and rGO.

Physical mixing. Physical mixing is a simple and convenient approach to fabricate MOF/graphene nanocomposites. Firstly,

Co-MOF-rGO	Excess metal-ion induced <i>in situ</i> growth	Annealing	3D encapsulated aerogel	—	PIBs	36
Ni-FePBA/GO	Excess metal-ion induced <i>in situ</i> growth	Stirring	3D porous aerogel	—	Derivative for the OER	40

MOFs and graphene are prepared in advance, and then directly mixed with each other to form the composite (Fig. 2a). In this way, a variety of MOF/graphene nanocomposites, including GO/Mo-MOFs,⁶⁶ rGO/HKUST-1,⁶⁷ Cu-MOF/rGO,⁶⁸ ZIF/GO,⁶⁹ PB/GO,⁷⁰ etc.,⁷¹⁻⁷⁴ were prepared in the early days by stirring, ultrasonication, or grinding the mixtures of MOFs and graphene, as shown in Table 1. However, most of the composites showed poor dispersion due to the weak interaction between MOFs and graphene. To overcome this issue, MOFs are usually modified to enhance the interaction between the mixtures. So far, several efficient modifiers have been reported, such as poly(diallyldimethylammonium chloride) (PDDA)^{75,76} and polydopamine (PDA).⁷⁷ With the decoration of modifiers, the surface of

MOFs will be charged. On the other hand, GO is intrinsically negatively charged because of the abundant oxygen-containing groups on the surface. So it is easy for GO to assemble with positively charged MOFs *via* electrostatic interactions. For example, a MIL-88-Fe/GO nanocomposite was fabricated by mixing GO and PDDA modified MIL-88-Fe crystals, which showed tightly interlocked interaction (Fig. 2b and c).⁷⁶ Besides, producing the strong π - π interaction with graphene is also an efficient way to improve the uniformity of MOFs.⁷⁸

Considering the influence of morphology on properties, the preparation of three-dimensional (3D) MOF/graphene nanocomposites has drawn a lot of attention due to their continuous porous network structures, which can provide large accessible

surface area, efficient charge and mass transport pathways, and robust mechanical strength. The 3D MOF/graphene aerogel was mainly prepared through a two-step method, involving the self-assembly of MOFs/GO hydrogel and the subsequent reduction process by a reducing agent, hydrothermal reaction, or annealing.^{79,80} Of particular interest, Xu *et al.* prepared various 3D graphene/MOF composites on a large scale and used them as precursors for further application in an all-solid-state flexible supercapacitor, which showed good rate capability with high specific capacitances (Fig. 2d–g).⁷⁹

***In situ* growth.** *In situ* growth is one of the most extensively used strategies for MOF/graphene nanocomposites owing to its facile and fast preparation. Through this way, MOFs grown on graphene will be more uniform, as well as having strong interaction with graphene. In a typical synthesis, GO can coordinate with metal ions first due to its abundant oxygenated functional groups followed by the *in situ* nucleation and growth of MOF nanocrystals when adding the ligands. For instance, wrinkled 3D microspherical ZIF-8@rGO composites were prepared by embedding *in situ* grown ZIF-8 nanoparticles between GO nanosheets, followed by high-temperature reduction self-

assembly (Fig. 3a–d). The microspherical composites possess a unique micro/nano hierarchy and show better oil–water separation ability than the individual components.⁸¹ Moreover, the *in situ* growth strategy has been employed in many other reports (Table 1).^{82–94}

The selection of solvents is an important factor in controlling the *in situ* growth rate and structure of MOFs. Due to the difference of ion movement and growth kinetics in different solvents, the sandwiched structure of ZIF–GO–ZIF composites can be synthesized in water instead of the coated structure in methanol, which provides a slower rate of ion depletion.⁹⁵ Shang *et al.* prepared CuBTC@GO composites using a mixed solvent strategy at a low temperature of 323 K for the first time. The authors found that *N,N*-dimethylformamide (DMF) promoted the motion of negative anions (BTC³⁻) toward the reaction with the cation (Cu²⁺) and helped the nucleation of CuBTC. Otherwise, CuBTC could not be formed at the relatively low temperature without adding DMF.⁹⁶

Different from the previous synthesis process, the modified GO interacting with ligands prior to metal ions can also affect the structure and therefore properties. Xu *et al.* fabricated a layered rGO/UiO-66-NH₂ sandwich hybrid using a noncovalent methodology for graphene modification combined with an *in situ* self-assembly technique.⁹⁷ As shown in Fig. 3e, GO was first functionalized with trimethyl-(2-oxo-2-pyren-1-yl-ethyl)-ammonium bromide (pyrene⁺) *via* π – π interaction. Then the attached pyrene⁺ served as an effective mediator to anchor 2-aminoterephthalate acid by electrostatic interaction. Finally, rGO/UiO-66-NH₂ was obtained after adding Zr⁴⁺ and a subsequent solvothermal reaction (Fig. 3f and g). The authors highlighted that pyrene⁺ functionalized GO was the key to avoiding its irreversible restacking and aggregation and forming the sandwich-like hybrids, which showed enhanced photocatalytic performance for aromatic chemical synthesis. In this way, many other MOF/graphene composites were prepared.^{98,99} Other studies also talked about the covalent functionalization of GO for MOF/graphene nanocomposites with improved properties.^{100–103} For example, Kumar *et al.* utilized benzoic acid to covalently functionalize the graphene basal plane, then the carboxylate groups of the modified graphene bonded with metal ions (M²⁺), followed by metal ions coordinating with the 2,5-dioxido-1,4-benzene dicarboxylate (DOBDC) linker to form MOFs (Fig. 3h). The as-prepared M/DOBDC-graphene (Fig. 3i and j) presented improved mechanical properties and CO₂ adsorption characteristics.¹⁰⁰

Recently, more and more efforts have been devoted to synthesizing 3D MOF/graphene nanocomposites through an *in situ* growth strategy, in which the solution immersion method is the most commonly used and most effective approach. Generally speaking, 3D graphene matrices (*e.g.*, graphene aerogel (GA) and 3D graphene networks (3DGNs)) with various sites for coupling with MOFs were first synthesized by hydrothermal assembly reaction,¹⁰⁴ chemical vapor deposition (CVD),^{105–109} *etc.*^{110,111} Subsequently, the obtained graphene matrix was immersed into the mixed precursor solutions of MOFs for further *in situ* growth as shown in Fig. 3k–n. The enhanced performance of the composites is reasonably attributed to the

synergistic interaction between functional MOFs and the 3D graphene matrix with a large surface area and interconnected porous structure.

Excess metal-ion induced *in situ* growth. The traditional *in situ* growth strategy employed to fabricate MOF/graphene nanocomposites usually yields relatively large MOF nanoparticles due to the rapid coordination reaction between metal ions and ligands, which suffer from insufficient available surface area and active sites. To address this issue, our group recently developed a versatile strategy of excess metal-ion induced *in situ* growth to fabricate MOF/graphene nanocomposites with small MOF nanocrystals, through which the obtained MOFs possess an average size below 10 nm.³⁹ As show in Fig. 4a, the method has a feasible mechanism: when excess metal ions were added to the homogeneous solution of GO and cyanomethylate ions, some of them reacted with the cyanomethylate anions to form Prussian blue (PB)/Prussian blue analogues (PBAs), and other excess metal ions adsorbed on the surface of PB/PBAs, which promoted the effective deposition of PB/PBA nanoparticles on GO by electrostatic and coordination interactions and inhibited the overgrowth of PB/PBAs. It should be noted that decreasing the content of metal ions would lead to the unsuccessful combination of PB/PBAs on GO, indicating the

necessity of excess metal ions in the synthesis system. The resultant PB nanoparticles have an average size of 5.2 nm, distributed uniformly on the GO surface (Fig. 4b–d).

Moreover, this method was also used to prepare a MOF/graphene nanocomposite with strong interfacial interaction. For example, our group synthesized a Co-MOF-rGO nanocomposite with Co-MOF nanocrystals tightly encapsulated in a 3D graphene network *via* strong chemical coupling interaction (Fig. 4e–i) and used it as an electrode material for potassium ion storage.⁴⁰ DFT simulation and experimental results revealed that the strong chemical interface between Co-MOFs and rGO could substantially enhance the adsorption and diffusion of the potassium ion within the MOF nanocrystals, which was the reason for the dramatic enhancement of electrochemical performance. Other MOF/graphene nanocomposites with sophisticated structures and superior properties have also been synthesized using this method.^{38,41,44,45,60,62,63,112}

To date, although a large number of MOF/graphene composites have been synthesized and applied in many fields, the MOF types in these materials are very limited, as a lot of work has focused on some common and pristine MOFs, such as Zn-MOF, Fe-MOF, Co-MOF, Ni-MOF, Cu-MOF, and Zr-MOF. The

exploration of other pristine MOFs (*e.g.* Al-MOF, K-MOF, conductive MOFs, *etc.*) and modified MOFs (decoration of organic linkers/metal centers, or introduction of other functional species into the MOF) with graphene may present amazing properties and needs to be further investigated.⁴³

Design and preparation of MOF/graphene-derived carbonaceous materials

MOFs have been considered to be a class of ideal precursors to synthesize nanoporous carbon materials *via* direct carbonization due to their large surface area, porous structure, and high carbon content.¹¹³ However, the application of these derived carbonaceous materials is greatly restricted because there are still some problems with the direct carbonization of dissociative MOFs. For example, the derived carbon materials inevitably aggregate together at high temperature owing to the high surface energy of MOF nanocrystals, resulting in the loss of many active sites. Besides, MOF-derived carbon materials always suffer from poor electrical conductivity due to the relatively low graphitization degree.^{114,115} In this regard, it is intriguing to explore the integration of MOF-derived carbon with graphene, which is expected to be an effective way to increase both density of active sites and electrical

conductivity.^{116–118} Consequently, various MOF/graphene-derived carbonaceous materials have been fabricated and show great potential in the field of energy storage and conversion.^{119–121} Among them, zeolitic imidazolate frameworks (ZIFs)/graphene-derived carbonaceous materials are intensively investigated, mainly due to the large surface area and effective nitrogen doping caused by the methylimidazole (MeIM) ligand, which are beneficial for the improved electrical conductivity, catalytic activity, capacitive performance, *etc.*⁶¹

Zhang's group prepared graphene-based nitrogen-doped porous carbon sheets (GNPCSSs) upon direct pyrolysis of the 2D sandwich-like GO/ZIF-8 composite and subsequent etching of the possible residual Zn species with acid (Fig. 5a).¹¹³ To ensure homogeneous and complete growth of ZIF-8 on GO, poly(vinylpyrrolidone) (PVP) was added to modify GO with the amide carbonyl groups, which would coordinate with Zn ions and facilitate the uniform nucleation of ZIF-8. The obtained GNPCSSs showed a sheet-like morphology and porous structure (Fig. 5b and c). The synergistic effect between the abundant nitrogen-doped carbon (NC) and continuous graphene conductive network with a well-defined porous structure is crucial for excellent oxygen reduction reaction (ORR) performance. It has been demonstrated that the mesoporous structure can serve as a reservoir for ion storage to facilitate electrolyte transport through shortened diffusion paths, thus enhancing the electrochemical performance.¹²² Nevertheless, ZIF-8-derived NC usually exhibits a microporous structure, which makes electrolyte percolation and ion transport difficult, leading to poor capacity retention at high discharge rates. Han's group reported that melamine could act as a pore-directing additive and expander for a mesoporous-rich carbon hybrid derived from a ZIF-8@GO precursor (Fig. 5d).¹²³ The mesopore formation was attributed to the gaseous byproduct evolution of melamine degradation at high temperature for the pore generation and expansion in the carbon architecture. And the mesoporous structure could be optimized by adjusting the content of melamine in the mixed precursor. The obtained melamine-modified samples showed a tiny hollow structure on the graphene sheets (Fig. 5e and f), facilitating efficient electrolyte percolation and ion transport, and bringing about superior Li-ion storage properties.

Although 2D carbon materials derived from MOF/graphene composites have shown unique advantages in many applications and made great progress, currently all of them are difficult to scale due to the time-consuming and careful assembly of MOFs on the surface of graphene. Compared with 2D carbon materials, 3D carbon architectures present faster electron/ion transport and higher ion-accessible surface area. Ding *et al.* developed a facile method to fabricate a 3D porous carbon framework (PCF) constructed from 2D heterostructured carbon nanosheets.¹²¹ As shown in Fig. 5g, the hybrid GO/ZIF-8 composite was easily prepared by vacuum filtration of a GO coated ZIF-8 composite, which was formed through electrostatic self-assembly of negatively charged GO nanosheets and positively charged ZIF-8 polyhedra. Then a 3D PCF composed of polyhedral-shaped hollow carbon coated with rGO was obtained after confined pyrolysis of a GO/ZIF-8 composite at 900 °C under

a nitrogen (N_2) atmosphere (Fig. 5h–j). The size of the polyhedral macropores can also be adjusted from the nanometer scale to the micrometer scale by employing ZIF-8 polyhedra with different particle sizes. The resultant PCF used as the host material for Li–S batteries exhibited a high discharge capacity and low capacity decay during the cycling test, which stems from their artful design and structure. In another study, Kotal *et al.* reported a scalable synthetic strategy for the formation of 3D porous graphitic nanoribbons anchored on graphene sheets (PGNR–G) with controllable morphology (Fig. 5k).¹²⁴ The formation mechanism was that the K_2CO_3 impurities that were generated during the carbonization of a rod-shaped potassium-based MOF (K–MOF) on GO intercalated into the layers of partially decomposed hollow rods, which facilitated the

formation of porous nanoribbons. As shown in Fig. 5l, such 3D PGNR–G structure with unzipped layered frameworks favoured faster ion intercalation/deintercalation and electron transport in the electrode. Fig. 5m–p show the 3D nanoarchitecture that unzipped PGNR anchored on wrinkled graphene sheets. When used as an ionic actuator, 3D PGNR–G exhibited breakthrough actuation performance owing to the synergistic effects of PGNR and graphene.

Design and preparation of MOF/graphene-derived single atom nanocomposites

Single atom materials with isolated metal atoms anchored on supports are emerging as a new frontier in energy conversion applications. The extraordinary characteristics, such as

maximum atom-utilization efficiency, special quantum size effect, unsaturated coordination configuration, unique electronic structure, and strong interaction with support materials, endow them with remarkable catalytic activity, selectivity and stability.^{125–127} However, during the synthesis and application of single atoms, they tend to agglomerate to form clusters due to their high surface energy, leading to a decrease in catalytic performance. Using MOF/graphene materials as precursors to prepare single atom nanocomposites is an effective way to overcome the challenge. On the one hand, MOFs with a regular arrangement of metal-based nodes and organic linkers are perfect templates to achieve uniformly dispersed metal single atoms. On the other hand, graphene enables a good conductivity of the derived composites. What's more, graphene is an ideal support for fabricating 2D MOF/graphene derivatives, which is beneficial for more exposed single atoms anchored on the surface, ameliorating the troubling issue that abundant single atoms are buried in MOF-derived solid carbon. To this end, several MOF/graphene precursors have been employed to prepare such satisfactory single atom nanocomposites.

Liu *et al.* prepared 2D porous Fe–N-doped graphene nanosheets (Fe–N/GNs) *via* a novel ZIF-8 “thermal melting” strategy by direct high-temperature pyrolysis of the Fe modified ZIF-8 “seeds”/graphene oxide (s-Fe/ZIF-8/GO) precursors at 900 °C (Fig. 6a and b).¹²⁸ The “thermal melting” phenomenon was caused by the high surface energy of s-Fe/ZIF-8 on GO, leading to the fusion and reorganization process under heat-treatment. Thus s-Fe/ZIF-8/GO was converted to 2D porous graphene nanosheets containing ultrathin porous carbon layers covered on the graphene nanosheets (Fig. 6c and d). Fig. 6e–g demonstrate that Fe and N were uniformly doped in Fe–N/GNs and abundant Fe isolated atoms coordinated with N atoms (Fe–N_x) were immobilized on the surface. It is worth mentioning that the Zn signal disappeared in the Fe–N/GNs, mainly because the ultrathin porous carbon reduced the diffusion distance of zinc atoms, making their evaporation easier at high temperatures. As a result, the Fe–N/GN electrocatalyst displayed efficient and stable ORR performances due to the following reasons: (i) single atom Fe active sites anchored on the surface of porous carbon were exposed completely to electrolytes, realizing their fullest utilization; (ii) the high specific surface area of the well-designed structure provided sufficient space to host a high concentration of atomic Fe–N_x sites; and (iii) the porous graphene ensured high electrical conductivity for fast electron transfer.

Yang *et al.* also synthesized a highly dispersed Fe–N_x catalyst derived from a graphene supported Fe–Zn-ZIF nanocomposite.¹²⁹ The authors emphasized that the introduction of graphene and PVP was helpful for regulating the size and morphology of ZIFs intercalated into the graphene sheets and avoiding iron particle agglomeration during pyrolysis. They obtained a high Fe–N_x active site content of 4.29%, surpassing that of most monodisperse non-precious metal catalysts reported. The as-prepared catalyst exhibited a respectable ORR performance with comparable onset and half-wave potentials in acidic medium. Up to now, significant progress has been made toward the fabrication of MOF/graphene-derived single atom

nanocomposites with fascinating structures. However, the related research is still in its infancy, and needs to be further conducted.

Design and preparation of MOF/graphene-derived metal oxides, sulfides, phosphides, carbides, and nitrides with sophisticated structures

Although MOF/graphene composites have achieved great success in the field of energy storage and conversion, they still suffer from some drawbacks, such as low conductivity (MOFs/GO), single pore structure, limited active sites and activity, and absence of multifunctionality, which prevents them from achieving high electrochemical performance and restricts widespread applications.^{17,23} In recent years, metal compounds (oxides, sulfides, phosphides, carbides, and nitrides) have attracted extensive interest due to their potential applications as electrode materials for supercapacitors, lithium-ion batteries, sodium/potassium-ion batteries, lithium–sulfur batteries, oxygen evolution and reduction reactions, CO₂ reduction, and so on.^{18,43} Encouragingly, these materials can be easily prepared by utilizing a MOF/graphene composite as a precursor. Since the spatially controlled metal node is embedded in the organic ligand environment of MOFs, the prepared metal compounds are usually encapsulated in carbon materials derived from organic ligands, which can result in superior performance. To date, significant progress has been made in the synthesis of lots of MOF/graphene-derived metal compounds with sophisticated structures.

Design and preparation of MOF/graphene-derived metal oxides. MOF/graphene-derived metal oxides can be obtained by two-step thermal treatment of the precursors.^{66,79,105,130–133} For instance, an rGO/Fe₂O₃ composite aerogel was fabricated by annealing a GO/Fe-MOF aerogel under a N₂ atmosphere at 450 °C, followed by another thermal treatment in air at 380 °C.⁷⁹ Men *et al.* reported that an rGO-wrapped Co@CoO composite with a yolk-shell structure (Co@CoO@rGO) could be achieved by pyrolysis of GO-wrapped ZIF-67 (ZIF-67@GO) in N₂ with 5 vol% H₂ at 750 °C. Then, by subsequent pyrolysis of Co@CoO@rGO in air at 350 °C, they obtained the rGO encapsulated hollow Co₃O₄ composite (h-Co₃O₄@rGO).¹³³ Hollow structures can afford large surface areas and shorter diffusion pathways, making it easier to access the electrolyte and reduce the mass transfer resistance, thus boosting the kinetics of electrochemical reactions. Zou's group developed a N-doped

graphene aerogel (NG-A) assisted method to prepare mono-disperse CoO_x hollow nanoparticles with highly defective surfaces by a simple thermal activation of bulk Co-MOF crystals (Fig. 7a).¹³² During the first thermal treatment at 750 °C under an argon gas flow, bulk Co-MOFs break into many Co-C core-shell nanoparticles on graphene. Pyrolysis temperature and the assisting graphene were two key factors that influenced the formation of such Co-C core-shell nanoparticles. The sample was then heated at 100 °C in air to obtain CoO_x/NG-A. When exposed to air, the highly active Co cores were oxidized, and the Kirkendall effect occurred, forming hollow cavities due to the different diffusion rates of O atoms in the air and core of Co atoms. The as-obtained hollow CoO_x displayed abundant edges or corner sites on the surface (Fig. 7b and c), which was helpful for enhanced ORR activity. As a robust Pt-free electrocatalyst for the ORR, the derived CoO_x/NG-A exhibited excellent

performance in alkaline electrolyte solution. In addition to the difficult two-step method, the evolved metal oxides can also be prepared by one-step carbonization of the MOF/graphene precursors in inert gas.^{94,134–140} As shown in Fig. 7d, Liang *et al.* synthesized an Fe₃O₄ nanoparticles/nitrogen-doped graphene aerogel (Fe₃O₄@NGA) hybrid by pyrolyzing MIL-88B-NH₂@NGA at 900 °C under Ar.¹³⁷ Besides, multi-component bimetal oxides (e.g., CoFe₂O₄,¹³⁵ NiCo₂O₄/NiO,¹³⁶ and CoO/MoO₂/CoMoO₄ (ref. 140)) or metal@metal oxide with core-shell structures⁹⁴ were also prepared in this way.

More conveniently, metal oxides can also be achieved by direct calcination of the MOF/graphene precursors in air.^{41,42,62,109,141–143} For example, our group synthesized a 3DG/Fe₂O₃ aerogel with porous Fe₂O₃ nanoframeworks wrapped within a graphene skeleton by employing a 3DG/PB aerogel as a template and thermal treatment at 250 °C under air conditions. The hierarchical structure provided a highly interpenetrated porous conductive network as well as abundant stress buffer nanospace for effective charge transport and robust structural stability during electrochemical processes.⁶²

To further improve the electrochemical performance, we deliberately designed a double-hole-heterostructure framework with holey Fe₂O₃ nanosheets (H-Fe₂O₃) tightly and conformably grown on holey reduced graphene oxide (H-RGO) *via* a facile calcination route by utilizing PB/GO composite aerogels as the precursor (Fig. 7e–h).⁴¹ During the annealing process in air, the transformed Fe₂O₃ nanoparticles were interconnected and fused to form a continuous holey nanosheet with abundant nanovoids due to the decomposition of the uniform and dense distribution of PB nanoparticles on GO. Such unique double-hole-heterostructure could accelerate electron and ion transport in unimpeded pathways and promote full utilization of active sites, resulting in enhanced electrochemical performance. We also reported that a coating layer is vital for the transformation of MOF/graphene composites. As shown in Fig. 7i, without the coating of polypyrrole (PPy), Co-MOF particles would transform into metal oxide at 350 °C in air. However, when coated by PPy, Co-MOFs under the same conditions would be *in situ* pulverized into ultrasmall MOF nanocrystals due to the protection of compact PPy layers,

which could significantly increase the decomposition temperature and maintain the component stability of Co-MOFs (Fig. 7j and k).⁴² Moreover, our group developed a universal microwave-assisted and confined-diffusion strategy to synthesize a series of hollow nanoparticles, including metal oxides, sulfides, and phosphides, using MOF/GO composites as precursors (Fig. 7l and m).³⁹ It can be seen that the obtained hollow Fe₂O₃ nanoparticles presented an ultrasmall size and thickness (Fig. 7n and o). The formation mechanism was that graphene that absorbed microwaves quickly created a high-energy environment to decompose PB into uniform core-shell Fe₃C@C nanoparticles owing to the redeposition of carbon gases generated in this process, then core-shell nanoparticles were further converted into hollow Fe₂O₃ through the nano-confined Kirkendall effect of the Fe₃C core and oxygen by the carbon shell. Notably, the traditional programmed heating strategy could not fabricate such exquisite nanostructure.

Design and preparation of MOF/graphene-derived metal sulfides. Metal sulfides, which show more enhanced conductivity than their corresponding oxide counterparts, are recognized as an important class of materials with potential applications in energy storage and conversion. The sulfur atoms with high electronegativity can extract electrons from metal atoms for facilitated electron transport.¹⁴⁴ Using a MOF/graphene composite as a precursor to synthesize metal sulfides has been extensively studied and various methodologies have been developed till now, including solid-state methods by annealing a mixture of precursor and S powder at high temperatures,^{72,76,145–150} solution-phase methods (*e.g.*, hydrothermal or solvothermal vulcanization reaction) using thioacetamide,^{107,151–153} thiourea,¹⁵⁴ or Na₂S^{92,155} as a sulfur source, and gas-solid reaction methods using H₂S/argon as a reducing gas¹⁵⁶ or direct carbonization of a S-containing precursor in inert gas.¹⁵⁷ Thus, many kinds of metal sulfide have been obtained, such as FeS,⁶⁰ FeS₂,^{63,145,146} Fe₇S₈,⁷⁶ NiS,¹⁵⁶ NiS₂,¹⁴⁷ Ni₇S₆,¹⁵⁴ Co₉S₈,¹⁵⁰ Co_{9–x}Fe_xS₈,⁹² CoFeS₂,¹⁴⁸ ZnSnS₃,¹⁵¹ CuCoS,¹⁵² CoZnNiS,¹⁵⁵ and so on.

As shown in Fig. 8a–c, Chen *et al.* synthesized a fancy composite assembled from a macroporous rGO-wrapped mesoporous hollow carbon polyhedral matrix with Co₉S₈ quantum dots embedded in it (denoted as (Co₉S₈ QD@HCP)@rGO) using S powder to vulcanize a ZIF-67@GO composite.¹⁵⁰ The authors found that the presence of coupled rGO not only benefited the growth of small nanoparticles, but also expanded the lattice parameters of Co₉S₈ QDs, facilitating sodium storage. Inspired by this work, our group designed a multi-scale nanostructure through one-step sulfidation of PB/GO aerogel in the same way (Fig. 8d).⁶³ The derived 3D aerogel, in which ultrafine FeS₂ nanocrystals were isolated and protected by porous nitrogen-doped carbon nanospheres (PNC) and then encapsulated into 3DG, effectively overcame some key issues of FeS₂, such as poor electrical conductivity, large volume expansion and agglomeration during electrochemical reactions, and sluggish charge diffusion, showing excellent sodium storage performance. Furthermore, Xie *et al.* prepared an RGO wrapped yolk-shell FeS₂/C composite *via* facile sulfidation of Fe@RGO, which was evolved by PB@GO in N₂ at high temperature.¹⁴⁶ In another

study, Xu *et al.* fabricated bimetal ZnSnS₃ nanodots encapsulated into the interconnected three-dimensional N-doped graphene framework (denoted as ZnSnS₃@NG) by a hydrothermal vulcanization reaction between a Sn/Zn-bimetal-organic framework and thioacetamide (Fig. 8e).¹⁵¹ Owing to the different redox potentials of the two metals, the self-matrix and self-conductivity effect would present simultaneously during the alloying/dealloying process, thus guaranteeing faster charge transfer and effective buffer for the reactive intermediate in lithium storage applications.¹⁵⁸ In addition, Qu *et al.* prepared a hierarchically porous hybrid electrode material through *in situ* sulfuration of a Ni-MOF-74/rGO architecture in H₂S/argon mixed gas (Fig. 8f). The as-prepared composite composed of α -NiS nanorods with highly exposed active surfaces decorated on rGO exhibited remarkable supercapacitor performance.¹⁵⁶

Integrating metal sulfide and metal oxide together to form a hybrid material is an effective way to improve the electrochemical properties because of the realized synergistic effects between good conductivity from the metal sulfide and high redox activity from the metal oxide. Ren *et al.* fabricated an integrated Co_{1–x}S/CoFe₂O₄@rGO nanoflower by *in situ* calcined sulfuration of Co_{0.8}Fe_{0.2}-MOF-74@rGO at 800 °C, and the temperature-controlled phase transition mechanisms were studied systematically (Fig. 8g–j).¹⁴⁸ At 600 °C, Co_{1–x}S was generated preferentially maybe due to the lower bonding energy of Co–S than Fe–S. When the calcination temperature was increased to 700 °C, the high bonding barrier of Fe–S was overcome, but only the CoFeS₂ phase formed since the activity of oxygen is insufficient to be involved in the reactions at this temperature. As it increased to 800 °C, the metal–sulfur bonds broke and the depleted oxygen components showed high enough activity to produce metal–oxygen bonds, leading to the co-existence of Co_{1–x}S and CoFe₂O₄. However, the high temperature of 900 °C would destroy the Co_{1–x}S/CoFe₂O₄ interfaces and reduce the Fe³⁺ to Fe²⁺ by the carbon species, which further bonded with S to generate stable FeS. Therefore, the appropriate temperature is essential for the formation of the desired sulfurized products.

Design and preparation of MOF/graphene-derived metal phosphides. Metal phosphides have had a great impact on energy storage and catalysis related applications due to their high theoretical capacity and activity, low cost, and environmental friendliness.^{159,160} Besides, like sulfur atoms with high electronegativity, phosphorus atoms in metal phosphides can also grip electrons from metal atoms and serve as proton acceptor sites in electrocatalytic reactions.¹⁶¹ However, pure metal phosphides face many serious problems during their applications, as can be seen everywhere, which compromises their electrochemical performance. Therefore, it is urgent to develop novel metal phosphide based materials to eliminate these issues. Luckily, it has been demonstrated that deriving metal phosphides from MOF/graphene composites is one of the most effective strategies to significantly improve the electrochemical performance because of the sophisticated structures of the derivatives. Generally, MOF/graphene derived metal phosphides are prepared through a phosphorization process in a tube furnace by using MOF/graphene or the metal/oxide

derived from it as a precursor and NaH_2PO_2 as a phosphorus source.^{91,98,111,112,162–170} Typically, the precursor and NaH_2PO_2 are placed in two separate positions in a porcelain boat with NaH_2PO_2 at the upstream side. Then the samples are heated to a certain temperature under an inert gas flow. In this process, PH_3 begins to be generated with the decomposition of NaH_2PO_2 and reacts with the precursor to form a metal phosphide based nanocomposite.

According to this method, Jin *et al.* fabricated a self-supported structure with CoP nanocrystals uniformly anchored on graphene nanoflakes, which vertically grew on

conductive carbon cloth (Fig. 9a and b).¹⁶² When used as a flexible sulfur host for Li-S batteries, the cathode delivered outstanding electrochemical performances owing to the effective immobilization and electrocatalytic interaction of lithium polysulfides with the CoP nanostructures and the synergistic effect of each component. Li *et al.* prepared porous core-shell FeP@CoP microcubes interconnected by RGO using PB as a reactant template. The core-shell structure could offer enough buffer space for volume changes and shorten the Na^+ diffusion distance for highly efficient sodium storage.¹⁷⁰ To achieve a larger active surface area and more exposed active sites, Yan

et al. prepared a Ni₂P/rGO composite with ultrasmall Ni₂P nanocrystals (average about 2.6 nm) anchored on rGO *via* one-step low temperature (275 °C) phosphorization of MOF-74-Ni/GO hybrids, which served as a bifunctional catalyst and showed high performance for overall water splitting.¹⁶⁸ Zhang *et al.* designed hierarchically porous structures composed of FeP hollow nanospheres embedded in a 3DG skeleton (3DG/FeP) through the spatially confined one-step thermal conversion of the 3DG/PB precursor with NaH₂PO₂ (Fig. 9c–e).¹¹² Such unique structures combined the 3D interconnected conductive network, discrete hollow nanoparticles, and graphene encapsulation effect together, which would promote charge transport and alleviate the volume change, imparting excellent potassium ion storage performance. The formation mechanism of hollow FeP was based on the nanoscale Kirkendall effects of PB shown in Fig. 9f.

To further improve the activity, introduction of another metallic element into the crystal structures of a monometallic phosphide is an effective method to manipulate the electronic state, thereby enhancing the electrochemical properties.¹⁷¹ Lu *et al.* synthesized a nanorod-like Fe–Co–P/N-doped graphene hybrid catalyst *via* a dual ligand coordination reaction followed by a phosphorization process. The obtained bimetal phosphide showed remarkably improved water splitting performance compared to its monometallic phosphide counterparts.¹⁶⁷ Li *et al.* encapsulated hollow (Co,Fe)P nanoframes into a N,P-codoped graphene aerogel for highly efficient water splitting.¹⁷² In addition, other bimetal phosphide composites (*e.g.*, Fe–Ni–P/rGO¹⁶⁶ and Ni_xCo_{1–x}P/rGO¹⁶³) have also been developed to achieve better performance. Different from the traditional method above, our group developed a novel ultrafast microwave-assisted thermal conversion route to synthesize bimetal phosphide/graphene composites. As shown in Fig. 9g–i, FeNiP/P-doped graphene (FeNiP/PG) and core@shell FeNiP@graphitized carbon/P-doped graphene (FeNiP/GC/PG) could be prepared within 20 seconds under microwave irradiation by employing a Ni–Fe PBA/GO/NaH₂PO₂ sponge as the precursor.⁴⁵ However, traditional programmed heat treatment only led to FeNiP/non-doped graphene (FeNiP/RGO). A high content of NaH₂PO₂ was essential for obtaining FeNiP/PG in this rapid conversion reaction because the decomposition of more NaH₂PO₂ absorbed more heat, leading to insufficient temperature for the formation of GC. Furthermore, Na₄P₂O₇ derived from NaH₂PO₂ was harmful for the microwave-based thermal transformation reaction.

Design and preparation of MOF/graphene-derived metal carbides and nitrides. Recently, metal carbides and nitrides have garnered much attention because of their high intrinsic conductivity, robust structural stability, abundant catalytic reaction sites, and low cost.^{173,174} Unfortunately, the unmodified pure materials make it difficult to meet the actual needs due to their unfavorable reaction activity. MOF/graphene-derived metal carbides and nitrides can significantly facilitate the reaction kinetics, mainly because the small particles encapsulated in the MOF derived carbon matrix will expose more active sites. What's more, graphene acting as an interconnected matrix offers a highway to promote the electron transfer. In

addition, the hierarchical architecture of the composite provides shortened pathways for mass transportation. As mentioned above, the microwave-assisted strategy developed by our group is an effective method to synthesize core–shell metal carbides@C structures.³⁹ Besides, most metal carbide derivatives are prepared through one-step carbonization of MOF/graphene precursors in inert gas.^{70,175–178} For instance, Tan *et al.* fabricated an rGO@C/Fe₃C composite with porous carbon coated Fe₃C nanoparticles loaded onto rGO nanosheets by *in situ* carbonization of rGO/Fe-MOFs at 700 °C (Fig. 10a–c).¹⁷⁶ When used as anode materials for battery–supercapacitor hybrid devices, the synergistic effect between Fe₃C and rGO enhanced the redox reaction of Fe₃C, resulting in excellent performance. Fang *et al.* designed a nitrogen-doped CoC_x/FeCo@C core–shell structure supported on rGO by a facile thermal treatment of Fe-doped Co₃[Co(CN)₆]₂ MOFs at 800 °C (Fig. 10d and e).¹⁷⁸ The carbides were formed due to the further reaction of the metal alloy and carbon shell. As a result, the obtained hybrid electrocatalyst showed excellent bifunctional properties for the ORR and OER owing to the multi-component synergistic effect. Besides, Fe/Fe₃C based materials have also received significant attention due to their durable catalytic

Fig. 10 (a) Graphic illustration of the fabrication and application of the rGO@C/Fe₃C material. (b) SEM and (c) HRTEM images of rGO@C/Fe₃C. Reproduced with permission from ref. 176. activity.^{175,177} However, for metal/metal carbide hybrids, it is difficult to control the reaction degree between the metal and carbon to precisely adjust the ratio of metal to carbide.

In general, MOF/graphene-derived metal nitrides are fabricated *via* ammonolysis of the corresponding precursors by NH₃ containing gas at high temperature.^{179–181} For example, Zou *et al.* prepared a robust trifunctional electrocatalyst of CoN_x anchored on a nitrogen-doped graphene aerogel (CoN_x/NGA) by annealing ZIF-67/GA at 500 °C under an ammonia atmosphere.¹⁷⁹ The CoN_x/NGA hybrid presented exceptional catalytic performance comparable to that of precious metals due to the plentiful dual active sites of CoN_x and N_xC and hierarchically porous structure. Kwag *et al.* synthesized 2D bimetal Fe₂Ni₂N/rGO nanohybrid sheets by nitridation of Ni_{2.25}Fe_{0.75}[Fe(CN)₆]₂/rGO nanosheets in a N₂/NH₃ co-atmosphere at 450 °C, which showed outstanding OER performance.¹⁸⁰ Furthermore, Liang *et al.* constructed core-shell Co₃Fe₇@Fe₂N nanoparticles supported on rGO by direct pyrolysis of FeCo-BTC@GO at 600 °C in NH₃ (Fig. 10f–h).¹⁸¹ The Co₃Fe₇ alloy core could promote electron conductivity, and the porous Fe₂N shell could provide abundant active sites of Fe–N–C apart from the enhanced stability of the material during the catalytic reaction. Thus, such unique structures exhibited superior ORR and OER reactivity. Bimetallic or heterostructure nitrides may provide more favorable electronic configurations than bare nitrides for better electrochemical performance, so further in-depth research into the structure–performance relationship is of great significance.

The application of MOF/graphene-derived nanocomposites in energy storage and conversion

Recently, pristine MOFs have aroused great interest among researchers for energy storage and conversion due to their remarkably high porosity and surface area, as well as tunable composition and pore structure. In particular, MOFs containing redox-active metal centers are of extraordinary interest for delivering electrochemical activity.¹⁷ However, the electronically insulating nature of most MOFs becomes a major obstacle to their electrochemical applications. Under this circumstance, developing intrinsically conductive MOFs has been recognized as a promising way to essentially solve this problem.¹⁸² Conductive MOFs inherit merits beyond traditional MOFs and they can also trigger faster electron transport during electrochemical reactions. Undoubtedly, conductive MOFs have broadened the applications of MOFs in supercapacitors, batteries, electrocatalysis, *etc.*¹⁸³ Nevertheless, it seems difficult for conductive MOFs to possess both high conductivity and high specific surface area simultaneously, which will compromise the electrochemical performance.¹⁸⁴ For the conductive MOF/graphene composite, graphene can not only serve as an ideal platform for the selective and uniform growth of conductive MOFs, but can also provide continuous pathways to ensure the high electrical conductivity of the entire electrode.¹⁸⁵ Besides, the presence of graphene may also affect the size and stability of conductive MOFs, like in traditional MOFs.

Conductive MOF/graphene-based materials are just in their infancy and more efforts are still required in the future. In this part, we mainly discuss MOF/graphene-derived nanocomposites for energy storage and conversion applications.

Supercapacitors

Supercapacitors (SCs), also known as electrochemical capacitors, are considered to be one of the most efficient and favored electrochemical energy storage devices, due to their various merits including fast charge–discharge rate, high specific density, long cycle life, and low cost.^{186,187} At present, SCs are widely used in energy/power requiring portable consumer electronics, and industrial devices.^{19,61} Based on the different charge storage mechanisms, SCs can generally be divided into two categories: electric double-layer capacitors (EDLCs) and pseudocapacitors. In EDLCs, electrical energy storage is based on the formation of a double layer of electrolyte ions on the surface of the electrode *via* electrostatic charge adsorption. Carbon materials, such as activated carbon (AC), graphene, and other porous carbons, are typical EDLC electrode materials. They possess a fast charge–discharge rate and long lifetime but low capacitance and energy density. In pseudocapacitors, the energy is stored through rapid and reversible redox reaction with electron transfer on the interface of the electrode and electrolyte. Conducting polymers and metal compounds are commonly used as pseudocapacitive electrode materials, showing large capacitance and delivering high energy density. However, they suffer from relatively poor cycling stability and low power density.¹⁸⁸ Thus, both EDLCs and pseudocapacitors have their inherent drawbacks, which limits their widespread applications that require high energy density and power density at the same time. It is well known that electrode materials dominate the performance of SCs. Ideal electrode materials for high-performance SCs need to have some vital characteristics, such as large specific surface area, hierarchically porous structure, superior conductivity, and more active sites,^{19,189} which are highly consistent with the properties of materials derived from MOF/graphene nanocomposites. In this regard, developing MOF/graphene-derived nanocomposites with sophisticated structures is an effective strategy for advanced SC applications.

Xia *et al.* prepared a nitrogen-rich porous carbon–graphene aerogel electrode (C/NG-A) through carbonization of Co-MOF/NG-A followed by etching in concentrated hydrochloric acid.¹³² As shown in Fig. 11a, C/NG-A was constructed from interconnected graphene networks and porous carbons, which provide a large ion-accessible surface area and efficient ion/electron transport pathways. As a result, the C/NG-A yielded a high capacitance of 421 F g^{−1} at 1 A g^{−1}, outperforming most reported nitrogen-doped graphene materials. Furthermore, even at a high current density of 50 A g^{−1}, 72.5% of its initial value was still retained, suggesting fast ion and electron transport within C/NG-A at high current density (Fig. 11b). When used in flexible all-solid-state supercapacitors (SSCs), the as-prepared supercapacitor could be bent without capacitance loss, as proved by the CV curves under different bending angles (Fig. 11c). Besides, the C/NG-A based SSCs also presented

outstanding cycling stability (Fig. 11d). Finally, the C/NG-A delivered a high power density (500 W kg^{-1}) at an energy density of $33.89 \text{ W h kg}^{-1}$. To achieve higher capacitance and energy density, various metal compound/graphene composites were designed, such as rGO/Fe₂O₃,⁷⁹ rGO/MoO₃,⁶⁶ rGO/Co₃O₄,⁹⁵ 3DGN/Mn₂O₃,¹⁰⁸ R-NiS/rGO,¹⁵⁶ rGO@C/Fe₃C,¹⁷⁶ CoZn-NiS@CNTs/rGO,¹⁵⁵ and so on.^{148,190-193} In particular, Xin *et al.* fabricated a 3D Co/Zn-S@rGO film through a mild *in situ* synthesis method and vulcanization of Co/Zn-MOF@GO film.¹⁹¹ Fig. 11e shows that Zn_{0.76}Co_{0.24}S nanoparticles were homogeneously embedded between rGO sheets, and also acted as spacers to prevent the rGO sheets from agglomerating. The resultant 3D sandwich film with porous and continuous networks was employed as a binder-free electrode for SCs and exhibited a high capacitance of 1640 F g^{-1} at a current density of 1 A g^{-1} . The assembled symmetric SCs (Co/Zn-S@rGO-7//AC) showed an ultra-high energy density (91.8 W h kg^{-1}) at a power density of 800 W kg^{-1} and excellent cycle stability (90.3% capacity retention after 8000 cycles at 10 A g^{-1}).

As mentioned earlier, hollow structures can provide large accessible surface areas and shorter diffusion pathways for electrolyte ions, which is beneficial for rapid mass transfer and improved electrochemical performance. Thus, it is very attractive to construct metal compound/graphene composites with

hollow structures for high-performance SCs. For example, Liu *et al.* synthesized a hierarchical hollow (Ni,Co)Se₂ nanocubes@rGO hybrid, in which the porous rGO not only acted as the conductive network to increase conductivity, but also served as a protector and space separator to maintain structural integrity.¹⁹³ Besides, the hollow (Ni,Co)Se₂ nanocubes could offer abundant electrochemically active sites, as well as enhancing the diffusion of ions in electrolyte (Fig. 11g). The as-prepared (Ni,Co)Se₂@rGO electrode achieved a high specific capacity of 649.1 C g^{-1} at 1 A g^{-1} (Fig. 11f). The resulting (Ni,Co)Se₂@rGO//AC hybrid supercapacitor delivered a high energy density of 52.6 W h kg^{-1} at a power density of 803.4 W kg^{-1} . In another separate study, Zardkhoshoui and co-authors assembled a hybrid supercapacitor by using a graphene wrapped multi-shelled NiGa₂O₄ hollow sphere as a positive electrode material and a graphene-wrapped yolk-shell NiFe₂O₄ hollow sphere as a negative electrode material.¹⁹⁰ Benefiting from their sophisticated structures, the fabricated asymmetric device showed an exceptional energy density of $118.97 \text{ W h kg}^{-1}$ at 1702 W kg^{-1} and an excellent robustness of 92.1% .

Interfacial engineering has been demonstrated to be a practicable strategy to improve the electrochemical performance. The modified interface can optimize the electronic environment, facilitate electron and mass transportation, and expose

more active sites, which is beneficial for fast electrochemical reaction kinetics.¹⁹⁴ Recently, an integrated $\text{Co}_{1-x}\text{S}/\text{CoFe}_2\text{O}_4@\text{rGO}$ nanoflower with abundant $\text{Co}_{1-x}\text{S}/\text{CoFe}_2\text{O}_4$ heterointerfaces was reported for high-performance SC application (Fig. 11i–l).¹⁴⁸ It yielded an ultrahigh specific capacity of 2202 F g^{-1} at 1 A g^{-1} (Fig. 11j), which was much higher than that of the individual components. In addition, it showed remarkable cycling stability with a capacitance retention of 90% after 20 000 cycles at 10 A g^{-1} (Fig. 11k). Furthermore, the fabricated $\text{Co}_{1-x}\text{S}/\text{CoFe}_2\text{O}_4@\text{rGO}/\text{AC}$ asymmetric supercapacitor achieved an excellent energy density up to 61.5 W h kg^{-1} at 700 W kg^{-1} . Density functional theory (DFT) calculation revealed that $\text{CoFe}_2\text{O}_4(100)$ exhibited a higher potential than $\text{CoS}(110)$, and the electrons could transfer from the conductivity-poor CoFe_2O_4 to conductive CoS through the heterointerfaces and then to rGO , thus realizing rapid Faraday reactions (Fig. 11l).

To sum up, morphology engineering, interface engineering, and doping engineering are effective methods to improve the electrochemical performance. However, it is hard for a single strategy to simultaneously meet the performance requirements of supercapacitors in practical applications, including large capacity, long cycle stability, and high power and energy density. In order to develop more efficient MOF/graphene-based materials, the synergy of combining these strategies may be a promising solution.

Lithium-ion batteries

In today's society, lithium-ion batteries (LIBs) are indispensable in people's daily lives. Since the commercialization of LIBs in 1991, they quickly governed the battery market owing to their large voltage, high energy density, and long cycle life,¹⁹⁵ and are widely used in many fields, such as portable electronic devices, hybrid electric vehicles, and power grids.^{196,197} In conventional LIBs, graphite is commonly used as the negative and lithiated transition metal oxides (e.g., LiFePO_4 , LiMn_2O_4 , and $\text{Li}[\text{Ni}_x\text{Co}_y\text{Mn}_z]\text{O}_2$) as the positive electrode materials.^{198,199} Although great progress has been achieved, they are still insufficient for the above applications due to the relatively low capacity, as well as low energy and power density.¹⁶ Recently, tremendous efforts have been devoted to fabricating MOF/graphene-derived nanocomposites with sophisticated structures, which are considered to be one of the most promising candidates to improve the LIB performance.

As an attractive anode material in LIBs, graphene shows a favourable low operating potential and long cycle life. However, it still suffers from unsatisfactory electrochemical activity, sluggish Li ion transport rate and insufficient accessible active sites, which leads to low energy and power density.^{200,201} To address these issues, researchers have paid attention to construct a porous structure or introduction of heteroatoms (e.g., N, P, S, and B) to the graphene frameworks. The porous structure can provide a larger surface area and more active sites for interfacial electron transfer reaction. Moreover, the pores can play a role in alleviating the volume change during the charging and discharging process to reduce capacity fading. Meanwhile, the doping of heteroatoms can improve the

conductivity and reduce the diffusion resistance of Li ions within graphene frameworks.²⁰² For example, nitrogen-doped porous graphene hybrid nanosheets derived from a ZIF-8/GO composite were reported to be a superior anode material for LIBs with a high reversible specific capacity of more than 700 mA h g^{-1} .^{118,120} Furthermore, reasonable control of the pore size distribution to the mesoporous range can accelerate the migration of ions, since the micropores will restrict the ion/electrolyte transport at high discharge rates.²⁰³ Therefore, Gayathri *et al.* prepared mesoporous-rich nitrogen-doped carbon@graphene nanosheets derived from a ZIF-8 precursor using melamine as a pore expanding agent and surface modifier, which exhibited high specific capacity and excellent long cycle life compared to the melamine-unmodified anode.¹²³

In contrast to the Li^+ intercalation storage mechanism of carbon materials, metal compounds based on reversible conversion reactions can provide higher capacity, energy density and power density.¹⁷ However, metal compounds often exhibit poor conductivity and large volume expansion during the charging and discharging process, which leads to sluggish electron transport and structure pulverization in the lithiation reaction, resulting in rapid deterioration of battery performance. Combining metal compounds with graphene to form a hybrid material can effectively solve these problems because of the excellent conductivity and confinement effect of graphene. Based on these understandings, various metal compounds/graphene have been synthesized, including $\text{Fe}_2\text{O}_3/\text{RGO}$,^{39,41,62,75,105} $\text{Fe-Co oxide}@GA$,⁸⁰ ZnO/C/rGO ,⁸⁶ $\text{rGO}/\text{Co}_3\text{O}_4$,^{95,130,133} $3\text{DGN}/\text{CuO}$,¹⁰⁹ MnO/C@rGO ,¹³⁴ $3\text{DG}@Co_{0.85}\text{Se}@C$,²⁰⁴ N-ZnSe@rGO ,⁸⁷ $\text{FeP}@C/\text{rGO}$,⁹⁸ $\text{ZnSnS}_3@\text{NG}$,¹⁵¹ *etc.*^{140,143} Among them, our group deliberately synthesized a 3D graphene/ Fe_2O_3 aerogel ($3\text{DG}/\text{Fe}_2\text{O}_3$) with porous Fe_2O_3 nanoframeworks well encapsulated within a graphene skeleton by employing a $3\text{DG}/\text{MOF}$ aerogel as a template (Fig. 12a).⁶² When used as a free-standing anode for LIBs, $3\text{DG}/\text{Fe}_2\text{O}_3$ exhibited an ultrahigh capacity of 1129 mA h g^{-1} at 0.2 A g^{-1} and excellent cycling stability (Fig. 12b). The superior performance could be generally ascribed to rapid electron/ion transport in the hierarchical structure and integrated structure of porous Fe_2O_3 protected by the robust 3DG network during the cycling process (Fig. 12c). To further promote ion transport in the graphene framework, we designed a $\text{H-Fe}_2\text{O}_3/\text{H-RGO}$ double-hole-heterostructure framework, in which holey Fe_2O_3 nanosheets are intimately grown on holey RGO (Fig. 12d).⁴¹ The in-plane nanopores could serve as open channels to promote ion and electron transport, as well as allowing for sufficient utilization of active sites throughout the highly compact electrode (Fig. 12e). As a result, the obtained $\text{H-Fe}_2\text{O}_3/\text{H-RGO}$ heterostructure anode delivered ultrahigh gravimetric, areal, and volumetric capacities. Besides, it also achieved extraordinary rate performance and cycling stability with a capacity retention of 96.3% after 1600 cycles (Fig. 11f).

Moreover, reducing the dimensions of active materials is an efficient route to enhance the electrochemical performance owing to the short distance for Li^+ to transport to the reaction sites. Our group developed a facile microwave-assisted and shell-confined Kirkendall diffusion strategy to prepare

ultrasmall hollow nanoparticles using ultrasmall MOFs/GO as a self-sacrificial template.³⁹ The obtained ultrafine hollow Fe₂O₃ nanoparticles were uniformly distributed on the surface of RGO (Fig. 12g). As expected, the ultrasmall hollow Fe₂O₃ nanoparticles on RGO (S-H-Fe₂O₃/RGO) delivered high capacities and superior rate capability, much better than those of a large hollow Fe₂O₃ nanoparticle/RGO composite (L-H-Fe₂O₃/RGO) and a solid Fe₂O₃ nanoparticle/RGO composite (Fe₂O₃/RGO) (Fig. 12h). Furthermore, the S-H-Fe₂O₃/RGO presented a highly reversible capacity of 684 mA h g⁻¹ with a capacity retention of 97.8% after 1200 cycles. In contrast, the L-H-Fe₂O₃/RGO showed obvious capacity decay after 850 cycles and lower capacity retention of 63.4% under the same conditions. This significant difference demonstrated that ultrasmall hollow Fe₂O₃ nanoparticles possessed better stress migration ability than the large ones, which broke into small pieces after cycling (Fig. 12i).

In addition to the MOF/graphene-derived nanocomposites discussed above as anode materials for lithium-ion batteries, MOFs have also been explored as cathode materials due to their redox active sites from both transition metal cations and/or organic linkers with redox active functional groups. Besides,

the regular channels of MOFs can facilitate Li⁺/Na⁺ diffusion and insertion.^{17,205} For example, Awaga and co-workers reported Cu-AQDC with redox activity on both the metal ions and organic linkers for cathode materials of LIBs. The charge-discharge curves involved two distinct electrochemical processes, that is, two-electron redox reaction from anthraquinone groups in the ligands and one-electron reaction from the Cu^{II}/Cu^I redox couple. As a result, Cu-AQDC exhibited a high specific capacity of 147 mA h g⁻¹.²⁰⁶ However, Cu-AQDC showed large capacity fading in 50 cycles, which was mainly caused by the poor electrical conductivity and highly localized electron density. The conductive MOFs may open up a new path for better electrochemical performance because their electrical conductivities and porous structures are favourable for electron and ion transport in the framework.²⁰⁷ The potential applications of conductive MOFs in lithium/sodium-ion batteries have been confirmed by Dincă and co-workers who showed that the prepared Ni₃(HITP)₂ MOF with high bulk electrical conductivity delivered high performance in electrochemical supercapacitors,²⁰⁸ as well as some other researchers using conductive MOFs in various battery systems, such as Na⁺/Zn²⁺

batteries,^{209,210} Li-S batteries,²¹¹ and so on. Moreover, the emerging new MOFs based on new ligands (*e.g.* organic Li-ion compounds) are promising cathode materials for lithium/sodium-ion batteries.²¹² What's more, we believe that the composites composed of traditional or conductive MOFs with graphene could show surprising performance due to their synergistic effect, which has been demonstrated by our group.³⁸

Sodium/potassium-ion batteries

In recent years, LIBs have expanded their application in the field of electric vehicles and large-scale electrical energy storage systems, and achieved considerable progress. Nevertheless, the

relatively scarce lithium resources and high cost greatly hinder the development.²¹³ Compared to lithium, sodium and potassium are much more abundant in the crust, and thus cheaper. Besides, sodium and potassium exhibit similar physical and chemical properties to lithium due to the same alkali metal group. Moreover, sodium/potassium-ion batteries have similar electrical storage mechanisms to that of LIBs. Therefore, sodium/potassium-ion batteries have garnered extensive attention and are expected to be potential alternatives to LIBs.^{34,214,215}

It has been proven that the commonly used graphite in LIBs is almost electrochemically inactive in sodium-ion batteries (SIBs) due to the energy instability of Na-graphite intercalation

compounds.^{216,217} In addition, many electrode materials suffer from sluggish reaction kinetics and inferior electrochemical activity because of the large ionic radius and heavier atomic mass of Na⁺, which leads to low specific capacity and poor cycling stability.²¹⁸ Therefore, it is urgent to develop desirable electrode materials for high performance SIBs. Meanwhile, thanks to the unique advantages mentioned earlier, MOF/graphene-based materials seem to be one of the ideal choices. For instance, our group synthesized a 3DG wrapped PB aerogel, and used it as a free-standing cathode material for SIBs. Excitingly, it delivered an extraordinary rate performance (84 mA h g⁻¹ at 25C) and long-term cycling stability (90% capacity retention after 1000 cycles at 10C), which was attributed to the highly efficient electron and ion transport in the whole electrode.³⁸ Furthermore, MOF/graphene-derived nanocomposites, especially sulfides,^{60,63,70,72,76,145,150} selenides,^{84,87} and phosphides,^{91,111,170} are widely studied for SIBs, due to their environmental benignity and higher theoretical specific capacities based on conversion reactions.

Morphology and structure engineering are effective strategies to boost the electrochemical properties of SIBs. The core-shell structure can buffer the volume change and prevent the active core material from pulverizing and aggregating during electrochemical processes.^{111,145} Our group fabricated an exquisite 3DG composite with a core-shell FeS@C encapsulated in 3DG by one-step thermal transformation of a 3DG/MOF composite, which exhibited excellent rate capacities of 363.3 and 152.5 mA h g⁻¹ at 1 and 6 A g⁻¹, and outstanding cycling stability with a capacity retention of 97.9% after 300 cycles at 1 A g⁻¹, when directly used as a flexible anode for SIBs (Fig. 13a-d).⁶⁰ In another study, Li *et al.* synthesized porous core-shell structured CoP@FeP microcubes interconnected by RGO through direct phosphorization of a GO wrapped core-shell Co(OH)₂@PB nanocomposite.¹⁷⁰ The well-designed structure showed high reversible capacity, and excellent rate capability and cycle life. A hierarchical hybrid structure with multi-compositional features will bring about an unexpected synergistic effect for enhanced SIB performance. For example, Shi *et al.* synthesized a sandwich hierarchical architecture with ZnSe nanoparticles fastened in N-doped carbon polyhedra anchored onto graphene with the modification of MoSe₂ nanosheets outside (ZnSe@N-C@MoSe₂/rGO, ZMSG) *via* a self-template of MOFs and subsequent selenization strategy (Fig. 13e).⁸⁴ The hybrid delivered a high rate capability of 224.4 mA h g⁻¹ at 10 A g⁻¹ (Fig. 13f) and extraordinary cycling performance that preserved 319.4 mA h g⁻¹ after 1800 cycles at 1 A g⁻¹, much higher than the performance of the single component (Fig. 13g). In addition, the performance of SIBs can be improved by constructing hollow structures and ultra-small nanocrystals.^{63,72,150}

Compared to sodium, potassium possesses a lower reduction potential (K: -2.93 V and Na: -2.71 V vs. the reversible hydrogen electrode (RHE)), which allows potassium-ion batteries (PIBs) to have higher energy densities than SIBs. Besides, K⁺ exhibits a weaker solvation effect due to weaker Lewis acidity, ensuring its quicker kinetics in PIBs.^{214,219} However, the larger ionic radius (K: 1.38 Å and Na: 1.02 Å) will

cause greater difficulty for K⁺ intercalation and a dramatic volume change during the discharge-charge process. Therefore, the electrode materials should be designed with large channels to promote the efficient insertion or extraction of K⁺. Due to the adjustable pore structure and relatively open channels as well as high specific surface area, MOFs are considered to be suitable for reversible K⁺ storage and transmission. Our group constructed a Co-MOF-rGO hybrid with Co-MOFs tightly encapsulated into rGO by growing Co-MOF nanocrystals on GO *via* synergistic coordination and electrostatic interactions and a subsequent annealing strategy.⁴⁰ We found that there existed a chemical-bonded interface between Co-MOF nanocrystals and rGO (Fig. 13h), and the strong chemical interaction at the interface could substantially enhance the adsorption energy and ion transport kinetics of K⁺ within the Co-MOF nanocrystals compared to the physical mixture of Co-MOF and rGO. The resultant Co-MOF-rGO with strong interfacial chemical couplings showed superior rate capacities of 422 and 202 mA h g⁻¹ at 1 and 5 A g⁻¹, and outstanding long-term cycling performance with 74% capacity retention after 2000 cycles at 2 A g⁻¹ (Fig. 13i and j). Besides, like LIBs and SIBs, some metal compound hybrids with distinguished structures derived from MOF/graphene composites (*e.g.*, hierarchically porous 3DG/FeP aerogel,¹¹² RGO wrapped FeS₂ hollow nanocages,¹⁴⁶ graphene encapsulated Co_{0.85}Se hollow cubes,²²⁰ and multicompositional ZnSe-FeSe₂/RGO composites⁸⁸) were explored as anode materials for PIBs. In particular, the flexible 3DG/FeP anode with hollow FeP nanospheres encapsulated within a 3D graphene skeleton delivered a high reversible capacity of 323 mA h g⁻¹ at 0.1 A g⁻¹ and ultrastable cycle life with a capacity retention of 97.6% at 2 A g⁻¹ after 2000 cycles (Fig. 13k-m).¹¹²

Lithium-sulfur batteries

Lithium-sulfur batteries (LSBs) are appealing as next-generation electrochemical energy storage devices because of their ultrahigh capacity (1675 mA h g⁻¹) and theoretical energy density (2600 W h kg⁻¹), and environmental benignity as well as the natural abundance of the sulfur cathodes.³⁴ Unfortunately, LSBs are facing some severe challenges, which hinder their commercialization. For example, the insulating nature of sulfur (electrical conductivity: 5 × 10⁻³⁰ S m⁻¹ at 25 °C) leads to inferior electron transfer ability and poor coulombic efficiency. Besides, the large volume change of sulfur (~80%) during cycling damages the integrity of the cathode structure. What's worse, the dissolution of intermediate polysulfides (Li₂S_{*n*}, 4 ≤ *n* ≤ 8) and their "shuttle effect" result in the loss of active materials. These drawbacks give rise to low capacity and poor cycling stability.^{115,221} To date, several approaches have been developed to address these issues, including the structural design of host materials, development of functional separators and new electrolytes, and modification of the lithium anode.²²² In this context, MOF/graphene composites and their derivatives play an important role in improving the performance of LSBs.^{223,224}

Heteroatom doped carbon has been demonstrated to be a favorable host material due to its large surface area, abundant

pore structure, and high electrical conductivity, as well as physical confinement and chemical adsorption of polysulfides. Chen *et al.* prepared a nitrogen-doped porous carbon anchored on graphene sheet (NPC/G) hybrid by thermal treatment of a ZIF/GO composite (Fig. 14a).¹¹⁵ In this architecture, the interconnected graphene could provide a highly conductive framework to facilitate rapid electron transport, and the abundant pore structure and doped N atoms could effectively trap polysulfides *via* both physical confinement and stronger chemisorption. Thanks to the multiple advantages, the NPC/G-based sulfur cathode (S-NPC/G) presented a high specific capacity of 1372 mA h g⁻¹ and good cycling stability over 300 cycles (Fig. 14b and c). In a separate study, a 3D porous carbon framework composed of hollow carbon polyhedra coated with rGO was chosen as a host material for LSBs, which suppressed the “shuttle effect” during the charge/discharge cycles due to the unique carbon structure and N doping, leading to high discharge capacities and excellent cycling stabilities.¹²¹ To further trap the polysulfides, Tan *et al.* coated sulfur-filled rGO/ZIF-8(C) derived from GO/ZIF-8 with poly(3,4-

ethylenedioxythiophene) (PEDOT) outside. The resultant composite cathode exhibited higher capacity and longer cycle life than that without PEDOT coating.²²⁵ Furthermore, Co,N-codoped porous carbon hosts showed enhanced LSB performance.^{226–229} For example, Wang *et al.* fabricated a free-standing sulfur host consisting of Co,N-co-doped porous carbon nanocages on 3D rGO (Co/N-PCN@rGO) through pyrolyzation of ZIF-67@rGO followed by acid leaching.²²⁶ After being penetrated by sulfur, the obtained cathode manifested a high discharge capability and an extremely low capacity decay rate, which was better than that of most reported carbon-sulfur-based cathodes.

Polar metal compound (*e.g.*, oxide, sulfide, and phosphide) based sulfur hosts derived from MOF/graphene nanocomposites were extensively studied due to their strong adsorption of polysulfides on polar surfaces.^{107,162,230–232} For example, rGO wrapped mesoporous MoO₂ microrods derived from Mo-MOFs were synthesized and used as the sulfur host in LSBs. The metallic MoO₂/rGO composite not only enhanced the transport of electrons and Li⁺ diffusion, but also restricted the

dissolution and shuttling of polysulfides. Moreover, the catalytic effects of MoO₂ facilitate polysulfide conversion kinetics. Therefore, the S-MoO₂/rGO cathode exhibited a high discharge capacity of 1145 mA h g⁻¹ at 0.5C and ultralong cycle life over 3200 cycles at 3C.²³⁰ Particularly, Xu and co-workers confirmed that the doping of nitrogen into cobalt oxides could provide additional affinity sites and strengthen the binding energy for polysulfide absorption.²³² As a result, the well-defined porous N-Co₃O₄@N-C/rGO synthesized by pyrolysis of ZIF-67 and subsequent rGO wrapping delivered a high reversible capacity of 1223 mA h g⁻¹ at 0.2C and excellent cycling stability of 611 mA h g⁻¹ retained at 2C after 1000 cycles (Fig. 14d–f). In addition, to increase the areal capacity, a higher sulfur loading is generally required. He *et al.* constructed a MOF-derived hollow Co₉S₈ array anchored onto a 3D graphene foam (Co₉S₈-3DGF) as a free-standing sulfur host for long-life LSBs. The Co₉S₈-3DGF/S cathode containing an ultrahigh sulfur loading of 10.4 mg cm⁻² realized an incredibly high areal capacity of 10.9 mA h cm⁻² at a rate of C/10 and still good cycling stability for 200 cycles.¹⁰⁷

Apart from being used as host materials, MOFs/graphene and the derived nanocomposites have also been applied as functional separator modifiers to mitigate the problem of polysulfide crossover. In this way, polysulfides can be efficiently confined in the cathodic side. Bai *et al.* reported a well-designed MOF@GO ionic sieve as a separator for improved LSB performance.²³³ Due to the significantly smaller micropore size (approximately 9 Å) of the used HKUST-1 than the diameters of lithium polysulfides, the soluble polysulfides were efficiently blocked at the anode side while Li⁺ ions were selectively sieved. In this case, LSBs with the MOF-based separator achieved a low capacity decay rate of 0.019% per cycle over 1500 cycles. Besides, Yu and co-authors fabricated a modified separator with electrocatalytic activity by dispersing Ni-MOF-74/GO derived graphene-supported Ni nanoparticles with a carbon coating (Ni@C/graphene) on a commercial glass fiber membrane (Fig. 14g). DFT calculation and an electrochemical investigation indicated that the Ni@C/graphene-modified separator could regulate the catalytic conversion of polysulfides and served as sulfiphilic sites to suppress the shuttle effect in the whole Li-S redox process. Benefiting from these merits, the corresponding LSBs showed a much better rate capability and superior cycle performances (Fig. 14h and i).²³⁴

Oxygen evolution and reduction reactions (OER and ORR)

The oxygen evolution reaction (OER) and oxygen reduction reaction (ORR) are two important parts of electrochemical energy conversion systems. The OER is a key electrochemical reaction involved in rechargeable metal–air batteries, fuel cells, and water electrolysis for oxygen and hydrogen generation with the mechanism of oxidation of water/hydroxyl ions on the surface of electrocatalysts and simultaneous evolution of oxygen gas. Meanwhile, the ORR is the reverse reaction of the OER, and is a critical process in metal–air batteries and fuel cells.^{235,236} The two reactions dominate the performance of these electrochemical energy conversion devices to a large extent.

Unfortunately, the inherent reaction kinetics of the OER and ORR are sluggish due to the multiple proton-coupled electron transfer procedures. To date, noble metal-based catalysts are still highly efficient for these reactions. However, their scarcity, high cost, and poor stability undoubtedly limit the large-scale applications.²³⁷ Therefore, developing low-cost and noble metal-free catalysts with reliable performance is highly demanded. Recently, research on MOF/graphene-based materials has provided an opportunity to develop efficient electrocatalysts.

MOF/graphene composites have been reported as direct active catalysts for the OER. Chen *et al.* developed a lamellar bimetallic MIL-53(FeNi) encapsulated in graphene aerogel-grafted Ni foam by an *in situ* solvothermal approach.¹¹⁰ The metal centers located in the edge-sharing octahedral MO₆ layers in MIL-53 helped to optimize the absorption energies of the oxygen-containing intermediates. And the porous graphene aerogel could act as a conductive bridge to connect MIL-53 crystals with Ni foam. As a result, the catalyst showed excellent OER performances in alkaline media. In another study, a highly active Co_xNi_{1-x} MOF/3DG electrocatalyst was prepared by a similar method for the OER, which exhibited a high catalytic activity attributed to the synergistic effect of Co and Ni in MOFs and the 3D structure of graphene.²³⁸ Besides, various MOF/graphene-derived composites (*e.g.*, metal or alloys,^{44,239} oxides,^{131,133,136,139} sulfides,^{153,154} phosphides,^{45,166–169,172} nitrides,¹⁸⁰ *etc.*¹⁵⁷) have been demonstrated as active OER electrocatalysts. For instance, our group developed an ultrafast microwave-assisted CVD-like method to convert a MOF/GO precursor into well-dispersed core@shell metal@NC nanocrystals with few-layer NC on RGO (M@NC/RGO) composite (Fig. 15a).⁴⁴ The huge heat rapidly generated under microwave radiation enabled the CVD-like generation of M@NC nanocrystals. It was believed that N-doping in the graphene shell could increase the density of states (DOS) near the Fermi level and few-layer NC could facilitate electron transfer from the metal core to the graphene shell. Benefiting from these structural advantages, the obtained FeNi@NC/RGO displayed a low overpotential of 261 mV at 10 mA cm⁻² in 1 M KOH and a small Tafel slope of 40 mV dec⁻¹, which was superior to that of a commercial IrO₂ catalyst (Fig. 15b and c).

The intrinsically unique structures provide infinite possibilities for the application of MOF/graphene-based materials in different electrocatalytic systems, including the ORR. Metal-free N-doped porous carbon/rGO composites derived from ZIFs/GO by high temperature carbonization have been extensively used as electrocatalysts for the ORR and presented comparable performance to commercial Pt/C, due to the synergistic effect between porous NC and graphene with regard to structure and composition.^{113,114,119,240} To further improve the ORR performance, embedding metal nanoparticles or single atoms into nitrogen-doped carbon (M–N–C, M = Fe, Co, *etc.*) is a good choice.^{116,128,129,241–244} On the one hand, the NC structure could play its original role to facilitate fast mass transport and electron transfer. On the other hand, the additional M–N_x active sites could promote oxygen adsorption and accelerate the ORR kinetics, thus leading to better ORR performance. For example,

Copyright 2019, Elsevier.

Wei *et al.* fabricated Co nanoparticles/N-doped porous carbon nanosheets through the pyrolysis of a sandwich-like GO/ZIF-8@ZIF-67 precursor at 900 °C, which was synthesized *via* a ZIF-8 seed-mediated deposition route (Fig. 15d).¹¹⁶ The obtained GO/ZIF-8@ZIF-67-900 catalyst delivered a high onset potential (~0.93 V vs. RHE), which was a slightly higher than that of Pt/C but better than that of porous NC nanosheets prepared under the same conditions (Fig. 15e). Furthermore, it showed better durability than Pt/C under alkaline conditions (Fig. 15f). To maximize the atom-utilization efficiency and achieve abundant M–N_x active sites, porous Fe–N-doped graphene nanosheets with single-atom Fe-sites on the surface were prepared, which exhibited an outstanding ORR activity.¹²⁸ Besides, many metal compounds derived from MOFs/graphene

were also developed for high-performance ORR catalysts.^{132,137,175,177}

In recent years, more efforts have been devoted to the development of efficient and stable bifunctional oxygen electrocatalysts due to their practicability. Up to now, various high-activity catalysts based on MOF/graphene composites, including M–N–C,^{245,246} bimetallic sulfides,^{92,152} metal nitrides,^{179,181} and metal oxides and carbides,^{94,178} showed great advantages and application potentials for the OER and ORR. In particular, cobalt-based nitride/graphene hybrids have attracted much attention because of their tailored electronic configuration of Co sites coordinated by N atoms and high inherent per-site catalytic activity. For example, a 3D nitrogen-doped graphene aerogel coupled with amorphous cobalt nitride (CoN_x/

NGA) was reported by Zou and co-authors (Fig. 15g).¹⁷⁹ The hybrid with a highly open 3D hierarchical NGA structure offered a highway for electron transfer and shortened pathways for mass transportation. Moreover, the abundant active CoN_x and N_xC sites stemming from amorphous CoN_x particles and NGA greatly boosted the electrochemical reactions. As a result, the integrated advantages guaranteed the high activity of CoN_x/NGA toward both the OER and ORR, which is comparable with noble metal catalysts (Fig. 15f and g).

CO₂ reduction

Catalyzing CO₂ transformations into valuable chemicals and fuels (*e.g.*, hydrocarbons, HCOOH, CH₃OH, C₂H₅OH, CO, *etc.*) is considered to be a promising way to alleviate global warming

and energy issues.²⁴⁷ Photocatalytic CO₂ reduction is an attractive approach owing to its direct use of visible light or sunlight as the energy source. A strong capability for CO₂ capture, abundant reaction active sites, high electron-hole separation properties, and wide optical absorption spectrum are imperative for high-efficiency photocatalysts. In this regard, MOF/graphene-based composites were reported to be efficient for photocatalytic CO₂ reduction.^{248–251} Wang *et al.* constructed a small-sized UiO-66-NH₂ nanocrystals/graphene (UiO-66-NH₂/GR) structure with a high dispersion and strong junctions of UiO-66-NH₂ on the surface of graphene *via* a microwave-assisted *in situ* growth and assembly route (Fig. 16a).²⁴⁸ The small-sized UiO-66-NH₂ nanocrystals could provide more active surface for trapping CO₂ and generating photogenerated

electrons, and the strong junctions could effectively promote the photoelectron-hole separation. In addition, the UIO-66-NH₂/2.0GR presented a more negative conduction band and lower band gap (Fig. 16b), which was beneficial for the enhanced ability of CO₂ reduction and longer-wavelength light absorption. Finally, the UIO-66-NH₂/2.0GR composite exhibited excellent activity and selectivity in the CO₂ photo-reduction to HCOOH under visible-light ($\lambda > 410$ nm) irradiation (Fig. 16c). In order to further extend the visible light absorption range to the full spectrum for increased solar light utilization, Sadeghi *et al.* used porphyrins to modify a MOF and designed a graphene-porphyrin based MOF photocatalyst, which showed high efficiency and selectivity of visible light-driven CO₂ to formate.²⁵⁰ In another case, a multi-component synergistic effect showed advantages for a high-activity photocatalyst. Meng and co-authors fabricated an oxygen-defective ZnO/rGO/UiO-66-NH₂ (denoted as OZ/R/U) Z-scheme heterojunction *via* a solvothermal method (Fig. 16d).²⁵¹ The CO₂ reduction reactions over the OZ/R/U heterojunction under visible light followed the Z-scheme photocatalytic mechanism (Fig. 16e), which could effectively decrease the recombination rate of photo-generated charge carriers while maintaining their high redox capabilities simultaneously. Thus, the Z-scheme OZ/R/U heterojunction exhibited high photocatalytic activity with the yields of CH₃OH and HCOOH reaching 34.85 and 6.40 $\mu\text{mol g}^{-1} \text{h}^{-1}$, respectively (Fig. 16f).

The electrochemical CO₂ reduction technology is also an effective route to convert CO₂ to value-added products. However, it suffers from a large overpotential, low selectivity and catalytic efficiency, mainly due to the high thermodynamic stability of CO₂ and possible multi-step reaction pathways during the proton-coupled electron transfer processes.²⁵² Therefore, developing highly active, selective and stable catalysts is crucial for practical CO₂ electroreduction. MOF/graphene-based materials provide an alternative solution for efficient CO₂ electroreduction. Zhang *et al.* prepared Cu/Cu₂O nanoparticles supported on vertically ZIF-L-coated nitrogen-doped graphene nanosheets (denoted as Cu GNC-VL) for electroreduction of CO₂ to ethanol.²⁵³ The obtained Cu GNC-VL catalyst presented a 3D structure with high electronic conductivity and uniformly dispersed Cu/Cu₂O active sites (Fig. 16g). Catalytic studies disclosed that Cu GNC-VL achieved a high current density of 10.4 mA cm⁻² at -0.87 V *versus* RHE and excellent faradaic efficiency of 70.52% for ethanol production in 0.5 M KHCO₃ solution (Fig. 16h and i), which was attributed to the synergy between the asymmetric chemical adsorption of CO₂ on Cu(111) and favorable thermodynamics and kinetics of C-C coupling on Cu₂O(111).

Summary and outlook

MOFs have been extensively investigated as a new class of inorganic-organic hybrid materials in various applications due to their high specific surface area, tunable pore structures, adjustable composition and morphological features. Nevertheless, the intrinsically poor electrical conductivity and low stability restrict their practical applications, especially in the

field of energy storage and conversion. Constructing MOF/graphene composites is an effective approach to alleviate these issues due to the synergic effects between MOFs and highly conductive graphene. More importantly, MOF/graphene-derived materials open up new paths toward their widespread applications. In this review, we first summarized comprehensively the latest methods of synthesizing MOF/graphene hybrids, including physical mixing, *in situ* growth, and excess metal-ion induced *in situ* growth, and the respective synthesis mechanism of each strategy involving the unique role of graphene was carefully discussed. Then we systematically discussed the formation mechanisms/methods of MOF/graphene-derived nanocomposites, including carbonaceous materials, single atom nanocomposites, and metal oxides, sulfides, phosphides, carbides, and nitrides with sophisticated structures, and their promising applications with a detailed analysis of the structure-property relationship in energy storage and conversion, such as SCs, LIBs, SIBs, PIBs, LSBs, OER, ORR, and CO₂ reduction. The current issues of various energy storage and conversion devices and how to improve the performance by employing MOF/graphene-based materials were also presented. We hope that this review will help researchers in related fields to have a comprehensive understanding of the recent progress in MOF/graphene-based materials, and stimulate further development of new high-performance materials for energy storage and conversion in the future.

Though great advances have been achieved in this field so far, several key challenges as well as opportunities regarding high-performance MOF/graphene-based materials and future practical application should be considered. (i) The strength of interface interaction between MOFs and graphene can not only significantly affect the charge transfer but also has an important impact on the ion adsorption energy and diffusion kinetics, thus impacting the electrochemical performance. Therefore, exploring MOF/graphene-based materials with strong interface interaction is very necessary for enhanced electrochemical performance. Meanwhile, constructing MOF/graphene-derived materials with heterostructures or heteroatom doped active components can precisely regulate the local electronic configuration for better properties. (ii) Reducing the size of MOF nanocrystals and their derivatives on graphene to expose more active sites for efficient electrochemical reactions without aggregation is of profound importance for high-performance applications. It is essential to develop a new and controllable strategy to synthesize such ultrasmall nanomaterials. (iii) Although MOF/graphene-derived materials exhibit a porous structure, the arrangement of these pores is usually disordered, which will lead to relatively limited mass transport kinetics compared to the ordered pore structure. Therefore, a material morphology with a hierarchically ordered porous structure needs to be pursued. (iv) A profound understanding of the formation processes of MOF/graphene-derived nanocomposites and the structure evolution as well as the structure-property relationships is in high demand, where theoretical calculations and *in situ* techniques will play important roles in future studies. (v) The coulombic efficiency and volumetric performance should be further increased without sacrificing the

capacity and rate through an elaborate balance of porosity, micro/nano-structures, *etc.* to meet the practical application. As a result, MOF/graphene-derived materials will definitely show a bright future toward energy storage and conversion.
