Minisci reaction of heteroarenes and unactivated C(sp³)-H alkanes *via* a photogenerated chlorine radical†

 Zi-Tong Pan, Li-Miao Shen, Fentahun Wondu Dagnaw, Jian-Ji Zhong, 
Jing-Xin Jian * and Qing-Xiao Tong *

Here, an efficient Minisci reaction of heteroarenes and unactivated C(sp³)-H alkanes was achieved using an inexpensive FeCl₃ as a photocatalyst. The photogenerated chlorine radical contributed to the HAT of C-H and subsequently initiated this reaction. Surprisingly, salt water and even seawater can act as a chlorine radical source, which provided an enlightening idea for future organic synthesis methods.

N-heteroarenes, such as benzothiazole and quinoline, are key structural motifs of many natural products, bioactive compounds, and pharmaceuticals (Scheme 1a).¹ The derivatizations of the functionalization of benzothiazoles and quinolines have attracted the attention of many researchers because of their wide existence. The Minisci reaction, which involves the addition of carbon-centered radicals to basic heteroarenes followed by formal hydrogen atom loss,² has provided a robust tool for the late-stage alkylation of N-containing heteroarenes because of its high atomic economy.³ But the photocatalytic derivatization and functionalization of alkylating reagents to produce alkylated carbon radicals are confined to active C(sp³)-H compounds. To date, only a few inactive C(sp³)-H compounds have been used as alkyl reagents. Besides, equivalent oxidants including peroxides,⁴ iodine reagents,⁵ persulfate (S₂O₈²⁻)⁶ and Selectfluor⁷ are required to promote this type of reaction by activating the substrate.

Alkanes, the major constituents of petroleum and natural gas, are widely distributed in nature and are mainly used as fuels, but few are utilized as economical chemical feedstocks.⁸ Unlike the C-H bonds activated by heteroatoms, aldehydes, benzylic and allylic groups,⁹ the unactivated C(sp³)-H bonds in

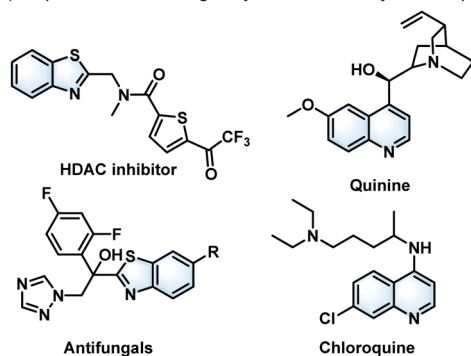

samples of alkanes have great intrinsic inertness and uncontrollable chemoselectivity due to their high bond dissociation energies (BDEs) of >95 kcal mol⁻¹.^{9b} Therefore, the functionalization of non-activated C(sp³)-H bonds has always been a research hotspot in organic synthetic chemistry. In recent years, the photocatalytic system based on the intermolecular hydrogen atom transfer (HAT) process was developed,¹⁰ which could seize the hydrogen atoms of inactive C(sp³)-H. In addition, the selectivity of the HAT process depends not only on the activated C(sp³)-H bond of the substrate, but also on the electronic effects of the HAT reagent as well as on spatial effects. However, current strategies involving C(sp³)-H bond homolytic cleavage mainly rely on a HAT strategy with bromine, nitrogen, and oxygen as the central electrophilic heteroatom radicals, and strong reducing catalysts or oxidants are required under harsh experimental conditions.¹¹

The chlorine radical (Cl•) is an effective HAT reagent that can cleave various C(sp³)-H bonds.¹² Chlorine (Cl₂)¹³ and N-chlorosuccinimide (NCS) are the two conventional reagents that produce Cl•, which in turn can afford alkyl radicals *via* the HAT process.¹⁴ Consequently, the chlorine radical (Cl•) formed from chloride ions (Cl⁻) as the HAT reagents has a greater potential for C(sp³)-H bond functionalization (Scheme 1b). In previous reports, noble metal catalysts¹⁵ and strong chemical oxidants¹⁶ were usually required in this process. The direct oxidation of soluble chlorides to Cl• requires a high oxidation potential (+ 1.21 V vs. SCE),^{15c} which is intolerant to some of the easily oxidized substrates. On the other hand, photoinduced ligand-to-metal charge transfer (LMCT) can well contribute to the generation of HAT reagents in photocatalytic systems.^{15a,17} However, a mild photocatalytic system avoiding the commonly used strong chemical oxidants and noble metal catalysts is still a serious challenge and is highly required for unactivated C(sp³)-H substrates. In recent years, there have been some reports about photoinduced iron-catalysed Minisci reactions.¹⁸ Herein, we describe a Minisci alkylation reaction of unactivated alkanes catalysed by inexpensive ferric

chloride (FeCl_3) under mild reaction conditions (Scheme 1c). Interestingly, salt water and even seawater can be used as chloride sources to promote this reaction, which ideally meets the concept of sustainable development and green chemistry.

For the outset, we began the optimization of the reaction conditions by choosing model substrates 4-methylquinoline (also called lepidine) (**a**) as a representative hetero compound and cyclohexane (**b**) as the model substrates (Scheme 2). After an extensive optimization study (Scheme 2, entries 1–10), the product **c** was obtained in a high isolated yield of 82% under the optimal conditions: lepidine (0.2 mmol, 1.0 equiv.), cyclohexane (0.5 mL, 20 equiv.), trifluoroacetic acid (TFA) (1.5 equiv.), 10% FeCl_3 catalyst, 50% LiCl additive, in 2.0 mL CH_3CN solvent, under irradiation of 385 nm light in an air atmosphere. The control experiments described in entries 2–3 showed that the reaction did not occur in the absence of light, and that there was a decreased yield under visible-light (> 400 nm) illumination. The light source was indispensable for this photocatalytic cross-coupling reaction of a heterocyclic compounds with cyclohexane. In addition, the reaction did not proceed effectively without the strong acid additive of TFA (entries 1 and 4–5), indicating that the protonation of the N-atom can activate the heteroarenes, a typical feature of the

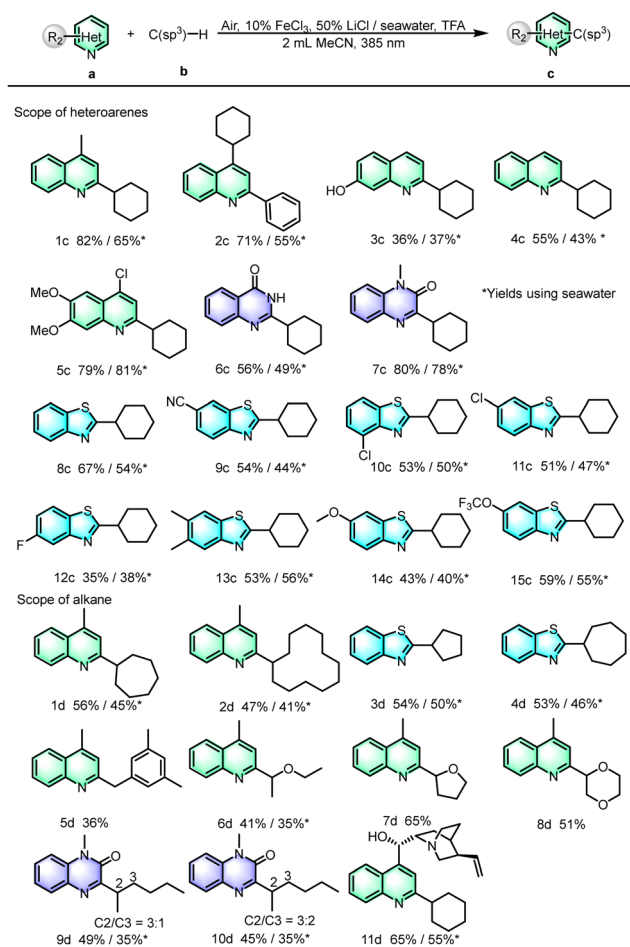

Entry	Light (nm)	Proton Sources	Catalyst	Additive	ATM ^[b]	c (%)
1	385	TFA	FeCl_3	LiCl	Air	82
2	-	TFA	FeCl_3	LiCl	Air	N. D.
3	400	TFA	FeCl_3	LiCl	Air	55
4	385	-	FeCl_3	LiCl	Air	Trace
5	385	AcOH	FeCl_3	LiCl	Air	12
6	385	TFA	-	LiCl	Air	N. D.
7	385	TFA	CuCl_2	LiCl	Air	63
8	385	TFA	FeCl_3	-	Air	25
9	385	TFA	$\text{Fe}_2(\text{SO}_4)_3$	Seawater ^[c]	Air	65
10	385	TFA	FeCl_3	LiCl	Ar	39

^[a] Reaction conditions. 0.2 mmol **a**, 0.5 mL **b**, 10% catalyst, 5% chloride and 25 μL TFA (1.5 equiv.), irradiated with a 3 W 385 nm LED at room temperature for 6 hours, dissolved in 2 mL acetonitrile solvent; ^[b] under air atmosphere or degassed with high-purity Ar for more than 15 min. ^[c] with 0.25 mL seawater containing 18.9 g/L of Cl^- .

Scheme 2 Optimization of the reaction conditions.^a

Minisci reaction. Copper chloride could also be used as the catalyst rather than ferric chloride, but the yield was relatively low (entries 1 and 6–7). These results indicated that iron cations played a key role in the catalytic process. The isolated yields of the product after addition of LiCl have significantly increased from 25% to 82%, compared to that without LiCl (entries 1 and 8). Considering the abundance of the element chlorine in natural seawater, we assumed that it may also be feasible to use seawater as the source of chlorine ions. The evidence showed that it was also effective to replace the addition of LiCl with seawater, and the yield is up to 65% (entry 9). After replacing the air atmosphere with high purity argon, the yield of this reaction was dramatically decreased (entry 10), hence based on the optimized reaction conditions, oxygen is a crucial factor to promote the radical reaction.

Under the optimal conditions, we expanded the range of different heterocyclic aromatic hydrocarbons. As shown in Scheme 3, quinolines substituted at the C4 or C2 positions reacted well to give the C2 or C4 coupling products (**1c–2c**), respectively, in good yields. In addition, for quinolines containing hydroxyl groups, the reaction was also tolerated, and the product (**3c**) was obtained in a medium yield. Moreover, for unsubstituted quinolines, the C2-substituted products were obtained in a moderate yield (**4c**). In order to study the applications of this type of reaction, bioactive intermediates, such as benzylation of 4-chloro-6,7-dimethoxyquinoline provided a fair yield (**5c**). Besides the quinoline, we also applied the optimized reaction conditions to heterocyclic compounds with two N atoms. To our delight, *p*-hydroxyquinazoline and quinazolinone also demonstrated satisfactory reaction efficiencies (**6c–7c**). Heterocyclic compounds containing S atoms and their derivatives, such as benzothiazole, are also very important

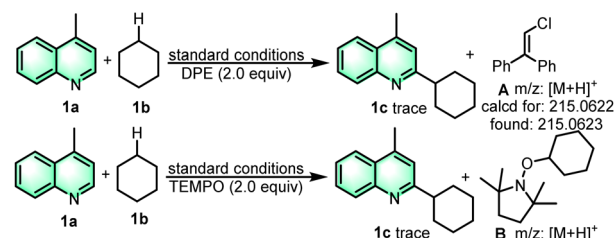

Scheme 3 Scope of heteroarenes and alkanes.

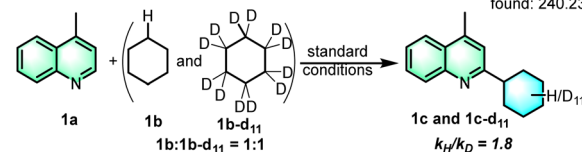

in organic synthesis. Our group previously reported the synthesis of alkylated benzothiazole derivatives from alcohols as alkylating agents,¹⁹ and here, we were surprised to find that the present reaction conditions were also applicable to the synthesis of alkylated benzothiazoles (**8c**). Many cross-coupling-useful functional groups, such as cyano (**9c**), chloro (**10c–11c**), fluoro (**12c**), methyl (**13c**), and ether (**14c–15c**) groups were all compatible and achieved moderate to good yields.

After investigating the reaction compatibility of heteroarenes, the substrate scope of unactivated alkanes was then examined. For instance, the corresponding products have been obtained in ordinary yields (**1d–2d**) for seven-membered cycloalkanes and even for cycloalkanes with up to twelve-membered rings, indicating that the chlorine radical is effective for the activation of non-activated hydrocarbon bonds with large positional resistance. Similarly, cyclopentane and cycloheptane can be coupled with benzothiazole in moderate yields to obtain coupling products (**3d–4d**). Furthermore, the C(sp³)-H substrates *m*-trimethylbenzene and ethers consisting of diethyl ether, tetrahydrofuran and 1,4-dioxane have been well reacted with quinoline to afford the C-2 substituted products in moderate to good yields (**5d–8d**). The linear alkanes *n*-pentane and *n*-hexane were tolerated for this reaction with moderate

(b) Kinetic isotope effect (KIE) experiment

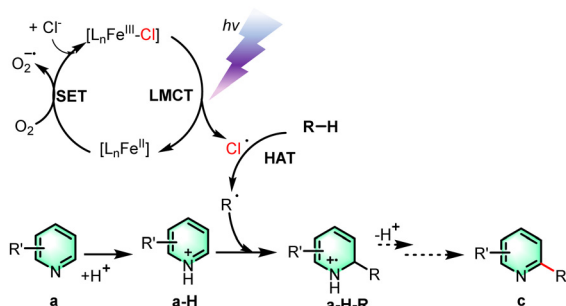

Scheme 4 Mechanistic investigation experiments.

yields (**9d–10d**). In addition, the reactions between cyclohexane and the drug molecule cinchonine can proceed, giving the corresponding product (**11d**) with isolated yields of 65% and 55% in the absence and presence of seawater, respectively. All the results demonstrated the good functional group tolerance and utilization potential of the reaction.

To have a better understanding of the reaction mechanism, 1,1-diphenylethylene (DPE) was added and 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) was added as a suitable radical scavenger (Scheme 4a). The experiment result shows that the reaction process was significantly inhibited, indicating that the transformation may undergo a radical pathway. The formation of adducts (**1c'**) and (**1c''**) indicates the generation of cyclohexyl and chlorine radicals.^{17c} A kinetic isotope effect (KIE) experiment was carried out to determine whether the hydrogen atom transfer (HAT) is the rate-determining step of the whole reaction process (Scheme 4b). The preparation of the products **1c-d₁₁** followed the general procedure using heteroarene **1a** and deuterated cyclohexane **2b-d₁₂** as the starting materials. The isolated products of **1c** and **1c-d₁₁** were obtained by column chromatography. The prominent isotope effect (*k_H*/*k_D* = 1.8) indicated that C–H homocleavage of cyclohexane was the rate-determine-step (Fig. S1, ESI[†]). The reaction quantum yield (Φ) was determined to be 23.6% (ESI[†], Fig. S2), indicating that there was no significant radical chain propagation process in this reaction (Scheme 5).

Based on the results of the mechanistic investigation experiments, a feasible reaction mechanism has been postulated. Firstly, the trivalent iron complex is excited by light and undergoes the process of LMCT to form a chlorine radical and a molecule of the divalent iron complex. The divalent iron complex then undergoes a single electron transfer process with oxygen to re-form the iron complex. The resulting chlorine radical can seize the hydrogen atom from the alkane and undergo a hydrogen atom transfer process to form an alkyl radical, which subsequently attacks quinoline at the C-2 position that was previously protonated by proton abstraction from TFA. The intermediate **a-H-R** is deprotonated and oxidized to form the product **c**. Moreover, verification experiments showed

Scheme 5 Proposed mechanism.

that **a-H-R** went through the elimination process to get to the final product (see the ESI†). We speculated that the halogen atom at the C-2 position is readily departed under the reaction conditions to add to the alkane substrate.

In summary, we reported a highly efficient, green and mild method for the unactivated C(sp³)-H functionalisation of alkanes by using ferric chloride as the catalyst. Heterocyclic aromatics including quinoline, benzothiazole and quinazoline, as well as compounds with diverse functional groups can effectively react. The most critical part of this reaction is the generation of chlorine radicals from Fe(III)-Cl LMCT processes. The method has the potential to become an important tool for the functionalization of advanced synthetic intermediates, which have many potential applications in medicinal chemistry. Combined with its simplicity and sustainability, it will help to simplify the synthesis of complex heterocyclic compounds in academia and industry.
