Regulating C–C coupling in thermocatalytic and electrocatalytic CO_x conversion based on surface science

Yawen Jiang, Ran Long and Yujie Xiong *

Heterogeneous thermocatalytic and electrocatalytic conversion of CO_x including CO and CO_2 to value-added products, which can be performed through three promising approaches – syngas conversion, CO_2 hydrogenation and CO_2 electroreduction, are highly important to achieving a carbon-neutral cycle associated with the continuing consumption of fossil fuels. Toward the formation of value-added C_{2+} products, precise regulation of C–C coupling requires rational design of catalysts in all the three approaches, which usually share similar fundamentals from the viewpoint of surface science. In this article, we outline the recent advances in catalyst design for controlling C–C coupling in syngas conversion, CO_2 hydrogenation and CO_2 electroreduction from the viewpoint of surface science. Specifically, the fundamental insights are provided for each conversion approach, which makes a connection between thermocatalysis and electrocatalysis in terms of catalytic site design. Finally, the challenges and opportunities are discussed in the hope of inspiring new ideas to achieve more efficient C–C coupling in thermocatalytic and electrocatalytic CO_x conversion.

1. Introduction

At present, fossil fuels are the main energy source in the world leading to energy and environmental issues. The reserves of fossil fuels on the earth are limited but the demand for energy for human development is never-ending. In the meantime, continuing consumption of fossil fuels has led to excess emission of carbon dioxide (CO_2). Consequently, the atmospheric CO_2 concentration has exceeded the safety limit of 350 ppm, and will predictably reach nearly 600 ppm by the end of this century.[1,2] It has been proposed that environmental issues such as global warming and ocean acidification are very relevant to such massive CO_2 emission.[3,4] For this reason, reducing the dependence on fossil fuels and the atmospheric CO_2 concentration are two urgent issues for the future development of mankind.

Chemical conversion of CO_x ($x = 1, 2$) to value-added products has gained increasing research interest, given its potential

Yawen Jiang was born in Anhui, China, in 1995. He received his B.S. in chemistry in 2018 from Xiamen University. Since then he has been a graduate student under the tutelage of Professor Yujie Xiong at the University of Science and Technology of China. His research interests focus on the design of electrocatalysts for carbon dioxide reduction.

Ran Long was born in Anhui, China, in 1987. She received her B.S. in chemistry in 2009 and Ph.D. in inorganic chemistry under the tutelage of Professor Yujie Xiong in 2014, both from the University of Science and Technology of China (USTC). After postdoctoral training with Professors Yujie Xiong and Li Song, she is currently an associate professor working at the USTC. Her research interests focus on controlled synthesis and catalytic applications of metal nanocrystals.

roles in addressing both the energy and environmental issues aforementioned. To achieve such chemical conversion, three heterogeneous catalytic processes – syngas conversion, CO_2 hydrogenation and CO_2 electroreduction – have been extensively explored. Syngas conversion produces hydrocarbons and oxygenates which can be used as liquid fuels or building-block chemicals.[5,6] The liquid fuels and chemicals produced from syngas are almost free of sulfur, aromatic compounds and other toxic impurities compared to those derived from crude oil so syngas has been considered as an ideal non-petroleum energy resource.[7] CO_2 hydrogenation offers a variety of products such as carbon monoxide (CO), methane (CH_4), formic acid (HCOOH), methanol (CH_3OH), hydrocarbons and higher alcohols.[8] This process can not only contribute to reducing the atmospheric CO_2 concentration, but also helps to shift energy consumption away from fossil fuels. In recent years, CO_2 electroreduction driven by renewable electricity under mild conditions has gained increasing research interest.[9] As the required electricity can be generated through photovoltaics or wind power, this approach can be easily combined with renewable energy. Moreover, various products such as CO, CH_4, HCOOH, and CH_3OH, and multi-carbon products can be obtained from electrocatalytic CO_2 reduction.

Product selectivity is a highly important parameter to chemical conversion of CO_x. As compared with C_1 products, converting CO_x to more valuable C_{2+} products (including C_2 products) is more attractive. However, the formation of targeted C_{2+} products is largely bottlenecked by the high kinetic barrier of C–C coupling and the competition with H–H and C–H bond formation, setting a grand challenge.[10] In order to overcome the challenge, the important key is to rationally design catalysts which can precisely regulate C–C coupling to produce the targeted C_{2+} products with high activity and selectivity. The catalyst design for regulating C–C coupling is typically achieved by controlling crystal facets, tuning catalyst sizes, adding promoters and other strategies, all of which have a great influence on the structural and electronic properties of catalysts based on surface science.

In recent years, significant breakthroughs have been made in syngas conversion, CO_2 hydrogenation and CO_2 electroreduction, between which a strong correction can be sorted out from the viewpoint of surface science. In this article, we will focus on the recently developed strategies for regulating C–C coupling to produce C_{2+} products in thermocatalysis and electrocatalysis. In the following sections, the fundamentals and typical catalyst design strategies based on surface science will be outlined for syngas conversion, CO_2 hydrogenation and CO_2 electroreduction. Finally, we will propose the challenges and opportunities for regulating C–C coupling by making a connection between thermocatalysis and electrocatalysis.

2. Regulating C–C coupling in syngas conversion

2.1 A brief overview of syngas conversion to C_{2+} products

Syngas is a mixture of CO and H_2 that can be obtained from natural gas, coal and biomass.[5] The research of syngas conversion has a history of more than 100 years. In 1902, Sabatier and Senderens synthesized methane through the catalytic hydrogenation of carbon monoxide.[11] In 1923, Fischer and Tropsch successfully obtained long-chain hydrocarbons from the hydrogenation of CO over Fe/ZnO and Co/Cr_2O_3 catalysts.[11] From then on, the production of long-chain hydrocarbons from syngas conversion became known as the Fischer–Tropsch (FT) synthesis. The FT technology has been put into practice in large-scale industrial production worldwide. Higher alcohols may also be obtained *via* syngas conversion. However, only two additional small-scale processes for higher alcohol synthesis (HAS) have been reported to reach commercialization based on syngas conversion.[6]

In the past century, various catalysts have been explored for syngas conversion.[7] Cobalt-, iron- and ruthenium-based catalysts are most suitable for the Fischer–Tropsch synthesis as the balance between CO dissociation and H_2 dissociation abilities can be achieved on the surface of these three metals.[7] In particular, ruthenium-based materials are the most active catalysts for syngas conversion. They offer a high selectivity for long-chain hydrocarbons and a low production of methane, but their high price hinders large-scale industrial applications. Iron catalysts show a higher selectivity to lighter hydrocarbons and have a high activity for the water–gas shift reaction (eqn (1), WGS), while cobalt catalysts are preferred to produce heavier hydrocarbons.[11,12] Essentially, the active phases of the two catalyst categories are iron carbides and metallic cobalt, respectively.[11,13] To obtain higher alcohols, the used catalysts can be classified into four categories: Rh-based, Mo-based, modified FT synthesis and modified methanol synthesis systems.[6]

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (1)$$

To better design catalysts, it is imperative to understand the mechanisms of syngas conversion. However, the reaction

Yujie Xiong received his B.S. in chemical physics in 2000 and Ph.D. in inorganic chemistry in 2004, both from the University of Science and Technology of China (USTC). After four-year post-doctoral training at the University of Washington in Seattle and the University of Illinois at Urbana-Champaign, he joined the NSF-NNIN at Washington University in St. Louis as the Principal Scientist. Starting from 2011, he has been a Professor of Chemistry at the USTC. He has published 170 papers with over 18 000 citations (H-index 67). His research interests include inorganic materials and devices for carbon dioxide reduction, nitrogen fixation, methane conversion, water splitting and chemical production.

process of syngas conversion is very complicated so the exact mechanism is still not fully understood. Fig. 1a illustrates a widely accepted carbide-based mechanism on the surface of traditional FT catalysts.[6,7,14–17] During the formation of hydrocarbons, CO is dissociated to form atomic species. Subsequently, the surface carbon species are hydrogenated to yield CH_x intermediates ($x = 0$–3). The generated CH_x can undergo further hydrogenation to produce methane or C–C coupling to form alkyl intermediates with different carbon numbers. The alkyl intermediates may be converted into paraffins and olefins through H addition termination and β-CH cleavage, respectively.[6] If the adsorbed CO* is further combined with the alkyl species, higher alcohols will be formed by the subsequent protonation.[18] In parallel, methanol can be generated by direct hydrogenation of the adsorbed CO*. As the C–C coupling of CH_x intermediates is uncontrollable on the catalyst surface, the hydrocarbon products are statistically distributed, which can be described by the Anderson–Schulz–Flory (ASF) model.[7,19,20] This model can be represented by the following formula:

$$M_n = (1 - \alpha)\alpha^{n-1} \quad (2)$$

where n is the number of carbons in the chain, M_n means the molar fraction of the hydrocarbon product with n carbons, and α represents the chain growth probability factor. Fig. 1b shows the ASF product distribution of hydrocarbons in a typical FT synthesis. From the mechanisms of FT synthesis, one can see that the coverage of H atoms and the adsorption of intermediate species on catalysts are the key factors for tuning C–C coupling, which would be affected by the parameters of catalysts.

As shown above, the process of syngas conversion involves a series of steps so it is very difficult to precisely control the process by using a single type of active site (*e.g.*, Fe or Co). According to the ASF law, the predicted maximum selectivities for C_2–C_4 (including both olefins and paraffins), C_5–C_{11} (gasoline), C_8–C_{16} (jet fuel) and C_{10}–C_{20} (diesel) hydrocarbons are 58%, 48%, 41% and 40%, respectively.[21] In recent years, the reaction coupling strategy based on bifunctional (or multifunctional) catalysts has been extensively studied in syngas conversion, achieving many significant breakthroughs. Notably, the C–C coupling mechanisms involved in the bifunctional catalyst system are different from carbide-based mechanisms on the surfaces of traditional FT catalysts. In general, one component in the bifunctional catalysts converts syngas to intermediates such as hydrocarbons, ketenes, methanol and dimethyl ether, and subsequently, the reaction intermediates enter another component (usually a zeolite) and undergo hydrocracking/isomerisation, hydrogenolysis, C–C coupling or dehydrogenative aromatisation to form liquid fuels, olefins or aromatics as final products. Such bifunctional catalyst systems and reaction mechanisms for syngas conversion were summarized and discussed in detail in a recent review by the Wang research group.[21]

2.2 Controlling crystal facets

Heterogeneous catalysis occurs on the surface of catalysts, where reactant molecules are adsorbed, activated and converted to final products through a series of elemental reaction steps. The adsorption and activation of reactant molecules and reaction intermediates are highly dependent on the exposed catalyst

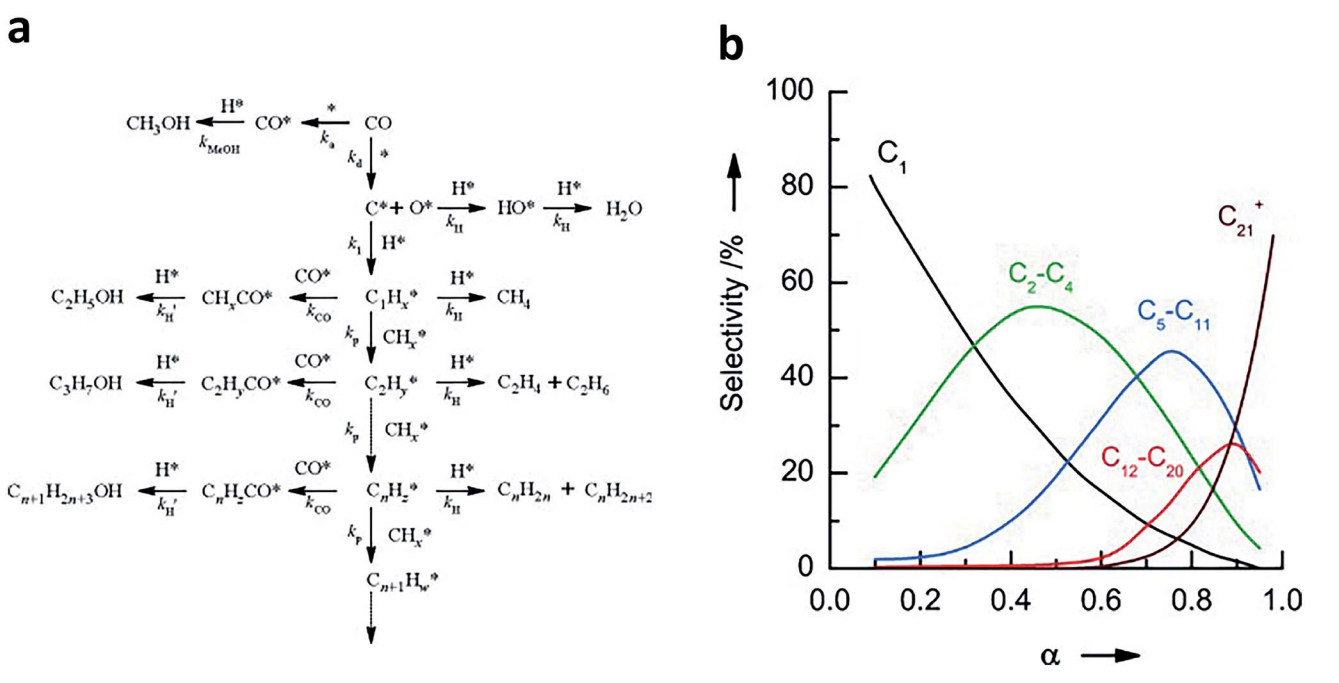

Fig. 1 (a) The carbide-based reaction mechanism for syngas conversion to hydrocarbons and alcohols. Reprinted from ref. 17 with permission from Elsevier. (b) Typical product distribution of syngas conversion predicted by the ASF model. The product selectivity is expressed as the molar percentage of a particular range of products on a carbon basis. Reprinted from ref. 20 with permission from John Wiley & Sons.

facets, due to the fact that crystal facets provide a knob for tailoring many parameters such as the surface atomic arrangement and surface electronic state.[22]

As such, controlling the crystal facets of the catalyst surface allows tuning C–C coupling to form specific C_{2+} products during the syngas conversion process. For example, Sun and coworkers reported a Co_2C nanoprism which exhibited unexpected activity for syngas conversion.[23] Using the Co_2C nanoprism as a catalyst, short-chain olefins can be produced with a high selectivity of up to 60% under mild Fischer–Tropsch reaction conditions, beyond the classical ASF distribution. Meanwhile, the selectivity for undesired methane was limited to about 5%. In sharp contrast, cobalt carbide had been generally considered inactive for C–C coupling as it tremendously produced methane according to earlier reports.[24] Transmission electron microscopy characterization (Fig. 2a and b) and DFT calculation (Fig. 2c and d) revealed that the (101) and (020) facets preferentially exposed on Co_2C nanoprisms were responsible for the high selectivity for the production of short-chain olefins and the low selectivity for methane formation. Based on DFT calculation results, CH_2CH_2 intermediates are well stabilized on $Co_2C(101)$, and the step of CH_x species hydrogenation to methane has high energy barriers on both $Co_2C(101)$ and $Co_2C(020)$. As such, exposing appropriate facets of catalysts can stabilize some key intermediates and shift selectivity to a specific range of products in syngas conversion.

2.3 Tuning the catalyst size

Size effects play an important role in heterogeneous catalysis. Tuning the particle size can not only change the surface-to-volume ratio of catalysts, but also alter their surface structure. For example, shrinking the size of catalysts can increase the fractions of corner and edge atoms,[25] forming more highly under-coordinated atoms at the exposed surface. In the meantime, the electronic state of the catalyst surface and the adsorption energy of reactant molecules can be varied through tuning the size.[22]

The size effects of cobalt catalysts have been extensively studied in the Fischer–Tropsch synthesis.[25] The size control offers the capability of tuning C–C coupling on the catalyst surface. de Jong and coworkers systematically studied the size effect of cobalt particles on the activity and product selectivity of the Fischer–Tropsch synthesis. They chose graphitic carbon nanofibers (CNFs) as an inert support material for loading Co particles with different sizes.[26] It turned out that the cobalt particles with a smaller size (<5 nm) showed a very high selectivity toward methane and a low turnover frequency (TOF). Under industrially relevant conditions (35 bar), the selectivity of C_{5+} products was promoted from 51 wt% to 85 wt% by increasing the cobalt particle size from 2.6 nm to 16 nm while the CH_4 formation was suppressed. Later, de Jong and coworkers further used steady-state isotopic transient kinetic analysis (SSITKA), which could resolve the coverage and surface residence time for reactants and reaction intermediates, to identify the origin of size effects in the FT synthesis.[27] The analysis revealed that forming Co particles with a small size (<6 nm) could reduce the surface coverage of CH_x species while promoting H coverage due to the increased fraction of highly under-coordinated atoms at the exposed surface. As a result, the C–C coupling and growth of alkyl chains became more difficult while methane formation was preferred. The investigation suggested that the cobalt catalysts should be controlled in the range of 6–8 nm to obtain a high selectivity to C_{5+} products.

2.4 Adding promoters

The addition of promoters is another way to tune C–C coupling in syngas conversion. The added promoters can help to increase catalyst activity, selectivity or stability.[28] Generally, promoters are classified into two categories according to their working mechanisms – electronic promoters and structural promoters, which can modify catalyst surface by changing surface electronic properties, blocking undesired active sites and altering the structure of the active phase. As a result, the addition of promoters can enhance the concentration of active surface intermediates,[29] increase the probability of chain growth[30] and facilitate the formation of active facets.[31] Typical promoters used in syngas conversion include alkali metals (*e.g.*, Na and K), transition metals (*e.g.*, Zn, Mn, Ti, and V) and nonmetallic elements (S).

Johnson *et al.* studied the effects of Mn promoters on the Co/SiO_2 catalyst for the Fischer–Tropsch synthesis.[28] The investigation revealed that, on Mn-promoted catalysts, the active sites near the interface between Co metal and MnO enhanced CO adsorption. Meanwhile, CO dissociation was facilitated by weakening the C–O bond through Lewis acid–base interaction near the interface, increasing the coverage of CH_x intermediates on the surface of catalysts. As such, fewer H species were available for methanation and paraffin chain termination. Consequently, the selectivity of C_{5+} products was promoted

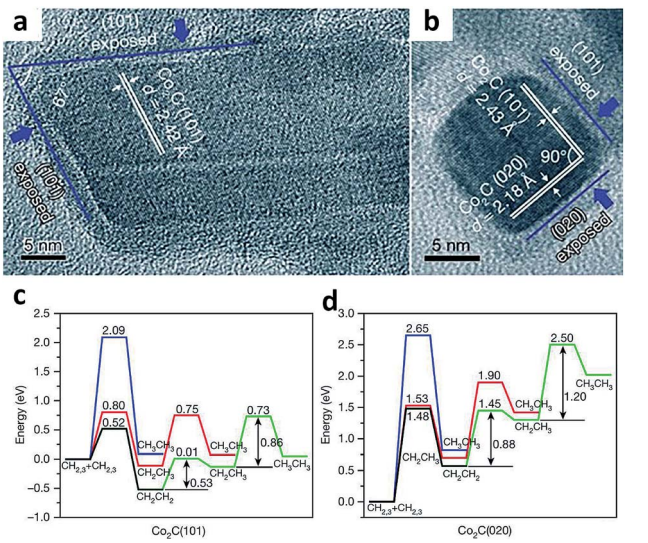

Fig. 2 (a, b) High-resolution TEM images of Co_2C nanoprisms. Energy profiles for pathways that lead to the formation of CH_2CH_2 and CH_3CH_3 on the (c) $Co_2C(101)$ surface and (d) $Co_2C(020)$ surface. Reprinted from ref. 23 with permission from Nature Publishing Group.

while excluding methane formation. However, excessive Mn loading may block more fraction of Co active sites.

In another case, de Jong and coworkers demonstrated that the addition of S and Na promoters to an Fe/α-Al_2O_3 catalyst achieved a high selectivity to C_2–C_4 olefins (about 50%).[30,32] Specifically, the Na promoter increased the probability of chain growth while the S promoter selectively blocked hydrogenation sites. Taken together, the two agents synergistically promoted the formation of C_2–C_4 olefins and suppressed the production of methane. Ma and coworkers fabricated Zn- and Na-modified Fe catalysts using a simple coprecipitation/washing method.[33] As shown in Fig. 3, the modified catalyst achieved an improved selectivity toward alkenes up to 70% for hydrocarbons. In such a catalyst, Zn served as a structural promoter to shrink Fe crystals, exposing more surface-active sites. In the meantime, Na acted as an electronic promoter to enable electron transfer from Na to Fe species, enriching electrons in the iron carbide active phase. The alteration of the surface electronic structure restrained the hydrogenation of double bonds and promoted the desorption of products, resulting in a high selectivity to alkenes.

2.5 Forming bimetallic catalysts

As compared with single metal catalysts, bimetallic catalysts often show enhanced catalytic performance as two metals may have synergistic effects on the surface reaction process. According to the mixing pattern of two metals, bimetallic catalysts can be classified into three main categories (Fig. 4): core–shell structures, heterostructures, and intermetallic or alloyed structures.[34] The three configurations in turn enable different surface structures. The bimetallic core–shell structure exposes one metal on the surface and confines the other as an inner core, in which the catalytic properties of the outer surface may be influenced by the inner metal. The bimetallic heterostructure forms a mixed interface between two regions of different metals, which is exposed as an active site for catalysis. The intermetallic or alloyed structures are homogeneous mixtures of two metals, between which the major difference is the distribution of metal atoms. The atoms of two metals are randomly distributed on the surface of the alloyed structure, while the surface of intermetallic structures is in a long-range atomic order.[34] Both atomic distribution configurations would impact catalytically active sites.

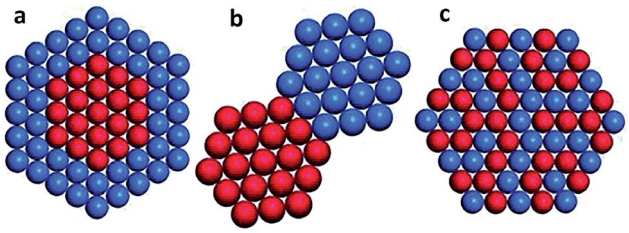

Fig. 4 Bimetallic nanocrystals with different configurations: (a) core–shell, (b) heterostructure, and (c) intermetallic or alloyed structures. Reprinted from ref. 34 with permission from John Wiley & Sons.

Developing core–shell structures with expensive Ru or Co as a shell and a cheap metal as a core is a promising strategy for reducing the cost of catalysts while maintaining high selectivity and activity. For instance, Haghtalab *et al.* developed core–shell structured Co@Ru/γ-Al_2O_3 catalysts.[35] The core–shell structured catalyst showed enhanced activity and selectivity for long-chain hydrocarbons in syngas conversion as compared with the Co/γ-Al_2O_3 catalyst owing to the higher intrinsic activity and C_{5+} selectivity of Ru. Increasing the thickness of the Ru shell can further improve the selectivity of C_{5+} products. Moreover, the catalytic performance of the shell metal may be influenced by the inner core metal. Calderone *et al.* developed a core–shell Fe@Co catalyst with the mean size of the magnetite core at 7 nm and the thickness of the cobalt shell at 1 nm.[36] After being supported on Al_2O_3 and further activation, the core–shell catalyst achieved a selectivity of about 40% for C_5–C_{27} hydrocarbons, lower than that of bare Co catalysts; however, the selectivity for oxygenates (10%) and olefins (20%) was higher than that of traditional Co-based catalysts. This observation demonstrated that the catalytic performance of the cobalt shell was maneuvered by the inner iron; however, the mechanism behind the phenomenon still remains unclear and needs further investigation.

Differently from the case of core–shell structures where one may affect the other, the alloyed structure of bimetallic catalysts typically shows a synergistic effect on syngas conversion by providing two active sites: one site for CO dissociation and the other for C–C coupling. Abatzoglou and coworkers found that the introduction of 4 wt% iron into a cobalt catalyst dramatically enhanced the selectivity for alcohol production from 2.3% to 26.3%.[37] In sharp contrast, the monometallic iron catalyst only offered a selectivity of 10.3%. The high selectivity toward alcohol formation was ascribed to the formation of a Co–Fe alloy. On the surface of the alloyed structure, Co and Fe were active sites for CO dissociation and CO insertion, respectively, so the optimization of Fe/Co ratios promoted the formation of higher alcohols.[18]

2.6 Designing bifunctional catalysts

In recent years, many breakthroughs have been made for converting syngas to targeted C_{2+} products such as olefins,[38,39] heavy

hydrocarbons (C_{5+})[40] and aromatics[41] using bifunctional catalysts. Usually, a bifunctional catalyst consists of a FT catalyst and zeolite. There exist four typical integration manners of the two components in the bifunctional catalyst system: dual-bed reactor model, physically mixing, core–shell structure, and loading of FT metal particles on a zeolite (Fig. 5).[7] The spatial locations of the two components in the bifunctional catalyst has a great impact on the selectivity for final products.[42] It should be emphasized that surface science also plays an important role in the design of bifunctional catalysts for regulating C–C coupling.

Recently, Bao and coworkers developed a stable composite catalyst containing $ZnCrO_x$ and a mesoporous SAPO zeolite (MSAPO), which achieved 80% selectivity for $C_2^=$–$C_4^=$ olefins and 94% selectivity for C_2–C_4 hydrocarbons at 17% CO conversion.[38] The selectivity of this process (oxide–zeolite, namely OX–ZEO) was far beyond the maximum (only 58% for C_2–C_4 hydrocarbons) predicted by the classical ASF model[38] (Fig. 6a–c). Oxygen vacancies on the surface of $ZnCrO_x$ played an important role in promoting CO activation to form CO_2 and surface *C species. The surface *C was in turn hydrogenated to CH_2 species, which underwent C–C coupling with CO to form a less reactive ketene (CH_2CO). The CH_2CO intermediate, which was detected by highly sensitive synchrotron-based vacuum ultraviolet photoionization mass spectrometry (SVUV-PIMS) during the *in situ* investigation of syngas conversion over $ZnCrO_x$ (Fig. 6d), went into zeolite pores and was finally converted to olefins inside the pores. The C–C coupling could be manipulated by changing the strength of surface acidity on the zeolite. Specifically, the medium acidity strength of the SAPO zeolite led to a high $C_2^=$–$C_4^=$ selectivity. It is worth pointing out that the confinement effects of zeolite pores also played a crucial role in tuning the selectivity for products.

The Wang research group found that the combination of a Zr–Zn binary oxide with a molecular sieve SAPO-34 could produce C_2–C_4 olefins with around 70% selectivity at about 10% CO conversion, also breaking the ASF distribution.[39] The Zr–Zn catalyst could efficiently convert CO to methanol and dimethyl ether (DME) in a wide temperature range, which were further transformed into C_2–C_4 olefins by SAPO-34. In this case, the density of Brønsted acid sites on the surface of SAPO-34 obviously affected the C_2–C_4 olefin selectivity. The Brønsted acidity of SAPO-34 originated from the substitution of Si for P or Al in the framework of the molecular sieve. As such, the Si contents could be tailored to prepare a series of SAPO-34 samples with different densities of Brønsted acid sites. According to the measurements of methanol conversion, the density of Brønsted acid sites on the surface of SAPO-34 determined the ratio of C_2–C_4 olefin/paraffin. A larger density of Brønsted acid sites led to a lower selectivity for C_2–C_4 olefins (Fig. 6e).

Apart from the two examples above, there is another strategy for designing bifunctional catalysts to regulate C–C coupling in syngas conversion, which integrates the active sites for CO activation and C–C coupling with the Brønsted acid sites in zeolites for C–C cleavage. For example, Tsubaki and coworkers fabricated mesoporous Y-type zeolite-supported cobalt catalysts (Co/Y_{meso}), bifunctional catalysts which could produce various liquid fuels with high selectivities by simply tuning the properties of Y_{meso}.[40] The Co catalyst converted syngas to a variety of hydrocarbons obeying the ASF distribution, and the Y_{meso} zeolite catalyzed the C–C cleavage of heavier hydrocarbons. In general, the Brønsted acidity of zeolites can lead to hydrocracking/isomerization of Fischer–Tropsch wax (C_{21+}). Guided by this assumption, an acidic zeolite Y_{meso}–H was prepared by a NH_4^+ exchange technique; however, it turned out that the Co/Y_{meso}–H catalyst showed high selectivity for undesired CH_4 and C_2–C_4 because excessive Brønsted acidity on Co/Y_{meso}–H led to overcracking of heavy hydrocarbons. By incorporating different cations into Y_{meso}, the Brønsted acidity could be tuned so as to regulate the degree of hydrocracking/isomerization of heavier hydrocarbons. Specifically, Co/Y_{meso}–Ce and Co/Y_{meso}–La possessed mild Brønsted acidities, which offered 74% selectivity for gasoline and 72% selectivity for jet fuel, respectively. In comparison, Co/Y_{meso}–K without Brønsted acidity produced a diesel fuel with 58% selectivity.

3. Regulating C–C coupling in CO_2 hydrogenation

3.1 A brief overview of CO_2 hydrogenation to C_{2+} products

CO_2 is a very stable molecule ($\Delta_f G^\theta = -396$ kJ mol^{-1}). For this reason, thermocatalytic reduction of CO_2 is a process that requires high energy input. The reaction of CO_2 with H_2 which has higher free Gibbs energy should make CO_2 conversion more thermodynamically favorable.[43] Moreover, this process has relatively faster kinetics compared with electrocatalytic CO_2 reduction. As such, CO_2 hydrogenation to fuels and valuable chemicals is regarded as a promising way to mitigate the energy crisis and reduce the environmental problems caused by elevated atmospheric CO_2 concentration.

Typically, C_{2+} products can be generated from CO_2 hydrogenation *via* two intermediate routes: CO intermediate route and CH_3OH intermediate route (Fig. 7a).[12] In the CO intermediate route, CO_2 is first transformed into CO *via* the reverse water–gas shift (eqn (3), RWGS) reaction. As a result, the more reactive CO is subsequently hydrogenated to hydrocarbons (or oxygenates). The mechanism of CO hydrogenation to C_{2+} products has been discussed above. For the latter route, the

CH_3OH intermediate can be obtained using a catalyst for methanol synthesis, which is further converted to hydrocarbons by methanol-to-hydrocarbon (MTH) catalysts. Specifically, the MTH includes methanol-to-olefin (MTO), methanol-to-propene (MTP) and methanol-to-gasoline (MTG) processes. Various mechanisms have been proposed for the formation of C_{2+} products in the MTH processes, including the oxonium ylide mechanism, carbine mechanism, carbocationic mechanism, free radical mechanism and hydrocarbon pool mechanism.[12] Among the mechanisms, the hydrocarbon pool mechanism in

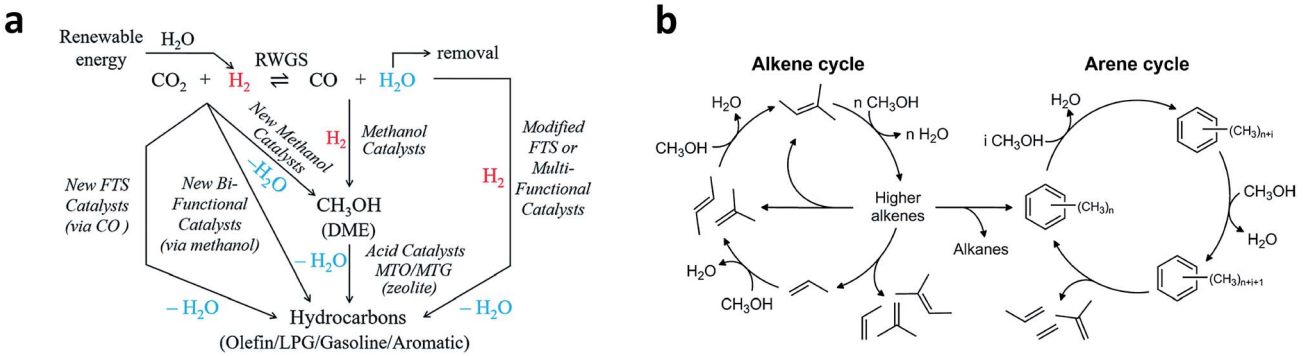

Fig. 7 (a) Schematic illustration of CO_2 hydrogenation to C_{2+} products *via* the CO intermediate route and CH_3OH intermediate route. Reprinted from ref. 44 with permission from Elsevier.

which aromatics and alkenes are important hydrocarbon pool compounds has been widely accepted. Larger hydrocarbons are formed after alkenes and aromatics are methylated with methanol (or dimethyl ether), and then crack or dealkylate to produce light alkenes and regenerate the starting compounds. The division between two classes of intermediates is usually referred to as the dual-cycle concept,[44] as shown in Fig. 7b. In such a mechanism, higher alkenes may be transformed into aromatics and alkanes through cyclisation and hydride transfer reactions, while light alkenes generated from aromatics may enter into the alkene cycle.

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad (3)$$

The above two routes for CO_2 hydrogenation can be achieved indirectly by using two-stage reactors;[12] however, direct hydrogenation of CO_2 to hydrocarbons or oxygenates is more economical and environmentally friendly. An ideal catalyst for the direct hydrogenation of CO_2 to hydrocarbons or oxygenates should possess high activity for both CO/CH_3OH formation and subsequent C–C coupling.[45] Iron-based catalysts are often used in CO_2 hydrogenation because they show outstanding catalytic properties for both RWGS and FT synthesis. In parallel, three categories of catalysts, including Cu-based catalysts, noble metal catalysts (Pd and Pt) and oxygen-deficient catalysts (In_2O_3 and ZrO_2), are usually utilized to produce methanol, followed by the MTH process catalyzed by acidic zeolites.[12] Although the catalysts based on noble metals (Rh, Pt, and Ru) and transition metals (Cu, Fe, and Co) have been widely employed to synthesize higher alcohols from CO_2 hydrogenation,[10,46] the reported activity and selectivity for higher alcohols are quite limited.[45]

3.2 Adding promoters

Like syngas conversion, the utilization of promoters is also a common strategy for tuning the selectivity for products in CO_2 hydrogenation. It is known that CO_2 is an acidic oxide so its adsorption occurs on the basic sites of catalysts. Adding an alkali metal such as K can increase the basicity of the catalyst surface, thereby enhancing CO_2 adsorption and suppressing H_2 adsorption. Choi *et al.* investigated the promoting effects of K based on an Fe/Al_2O_3 catalyst.[47] According to chemisorption studies, H_2 was only adsorbed on Fe while CO_2 was most likely adsorbed on the K sites. The addition of K enhanced the ability of CO_2 chemisorption and blocked the Fe sites for H_2 adsorption. As such, the coverage of CH_x species generated from CO_2 was increased on the catalyst surface while reducing the H coverage, promoting the C–C bond formation. Xu and coworkers reported that the Na promoter could not only enhance the surface basicity of the Fe_3O_4 catalyst to promote CO_2 chemisorption and inhibit the hydrogenation of double bonds, but also acted as a structure promoter to form an active iron carbide phase.[48]

Other transition metal promoters (*e.g.*, Mn, Cr, and Mo) can improve selectivity to long-chain alkanes. Dorner *et al.* suggested that the addition of Mn promoters to supported Fe-based catalysts led to an increase in the selectivity for unsaturated higher-chain hydrocarbons by repressing methane formation.[49] Such a change in product distribution was caused by blocking hydrogenation active sites on the Fe surface with Mn promoters. Without sufficient H coverage, methanation and paraffin chain termination would be suppressed to facilitate the production of higher-chain hydrocarbons.

3.3 Forming bimetallic catalysts

Direct hydrogenation of CO_2 to valuable C_{2+} products with high activity is a highly challenging task. Single metal catalysts are often incapable of offering the function to overcome the limitation of chemical equilibrium during the process of CO_2 hydrogenation. Specifically, the CO generated from RWGS has low partial pressure in a CO_2/H_2 atmosphere due to thermodynamic constraints, limiting C–C coupling.[50] Forming bimetallic catalysts can potentially circumvent the limitation of chemical equilibrium and improve the catalytic activity and selectivity for CO_2 hydrogenation, benefiting from the synergistic effects on the surface reaction process mentioned above.

For instance, Wang *et al.* synthesized an Fe–Cu bimetallic catalyst which improved the production of C_2–C_7 hydrocarbons and suppressed methane formation in comparison with the corresponding monometallic catalyst.[51] The selectivity to C_{2+} hydrocarbons was enhanced by the synergistic effects of bimetallic metals. Cu functioned as an active site for the generation of CO or CO-like intermediates *via* RWGS, while Fe sites catalyzed C–C coupling of the CO intermediate to form hydrocarbons. The CO intermediates generated on Cu sites were subsequently consumed on Fe sites. As a result, the driving force for the RWGS could be enhanced, generating more CO intermediates on the catalyst surface. The improved surface CO coverage led to forming more CH_x species on Fe sites, eventually promoting the production of long-chain hydrocarbons.

3.4 Designing bifunctional composite catalysts

In recent years, more research efforts have been devoted to the conversion of CO_2 to olefins, gasoline and other valuable C_{2+} products using bifunctional catalysts,[52–54] given that the bifunctional catalysts have achieved such a big success in syngas conversion. Typically, a bifunctional catalyst for CO_2 hydrogenation consists of a catalyst for methanol synthesis and a zeolite for further conversion of methanol intermediates to final products.[4,53,55] In parallel, the process that is not mediated by methanol has also been reported.[52]

It is worth mentioning that the oxygen vacancies and surface acidity of the zeolite play vital roles in the design of bifunctional catalysts for CO_2 hydrogenation. Sun and coworkers recently reported an In_2O_3/HZSM-5 bifunctional catalyst with excellent durability which could yield C_{5+} hydrocarbons with a high selectivity of 78.6% while the selectivity for methane was limited to only 1% (Fig. 8a and b).[53] DFT calculations showed that CO_2 was chemisorbed at the oxygen-vacancy sites on the surface of reducible In_2O_3 and hydrogenated to CH_3OH through several intermediates (Fig. 8c). The CH_3OH intermediate entered into the HZSM-5 zeolite and was further converted to hydrocarbon products at the surface acidic sites of the zeolite *via*

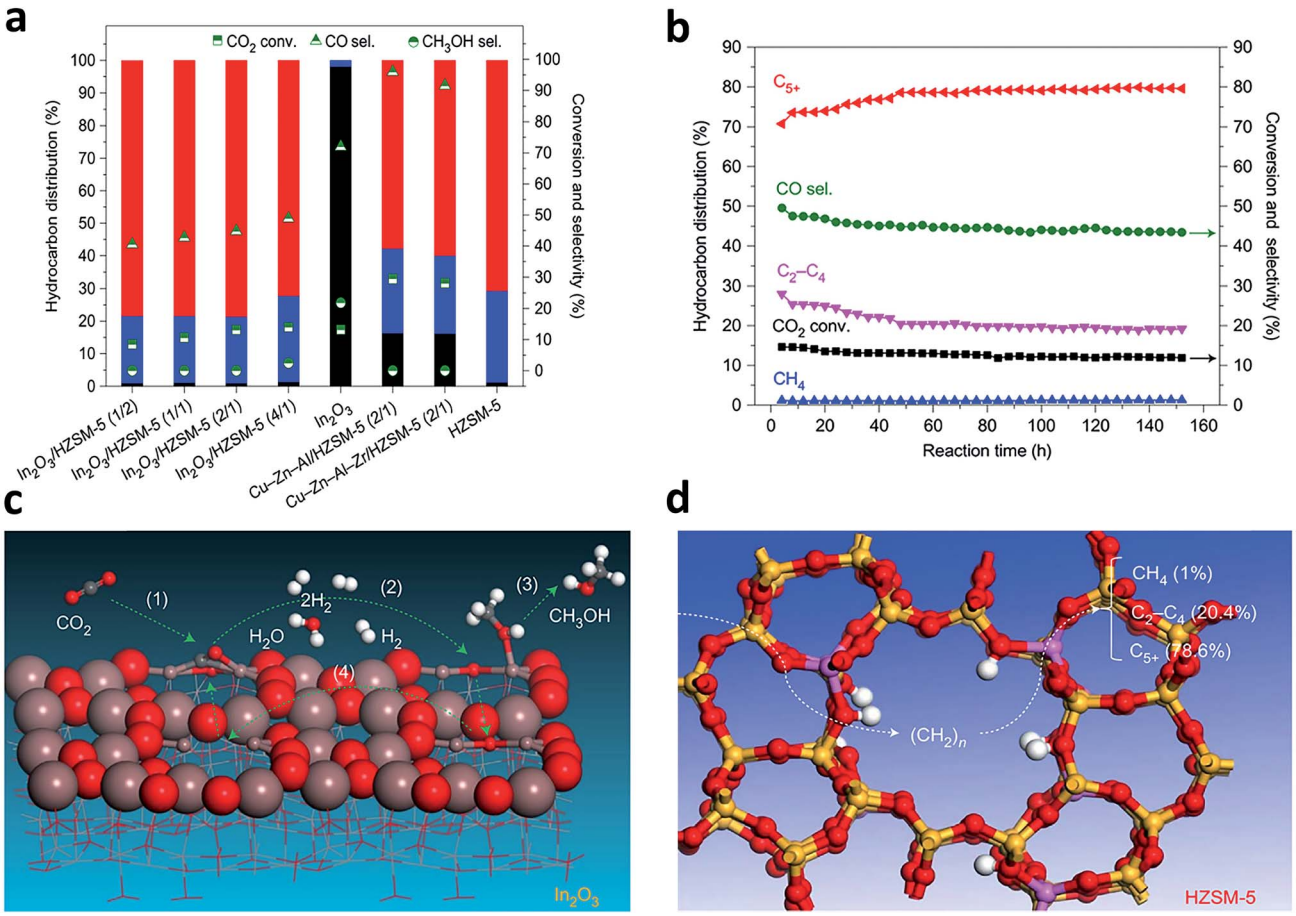

Fig. 8 (a) Catalytic performance of CO_2 hydrogenation over various bifunctional catalysts that contained Cu-based catalysts or In_2O_3 and HZSM-5 with different mass ratios, in reference to the stand-alone In_2O_3 catalyst and HZSM-5. a hydrocarbon-pool mechanism (Fig. 8d). Wang and coworkers developed a bifunctional catalyst composed of $ZnGa_2O_4$ and SAPO-34 which achieved 86% selectivity for C_2–C_4 olefins at 13% conversion of CO_2.[55] In that case, the oxygen vacancies on the surface of $ZnGa_2O_4$ were also responsible for CO_2 activation.

It should be noted that the water generated through the RWGS reaction is detrimental to the process of CO_2 hydrogenation.[4] Excessive water may cause the deactivation of surface acidic sites on the zeolite, which severely holds back C–C bond formation and leads to a low production of C_{2+} products. For this reason, it is necessary to remove the generated water timely. To this end, the hydrophobic modification of the zeolite surface helps to solve the problem caused by the produced water. Fujiwara *et al.* developed a composite catalyst consisting of a Cu–Zn–Al oxide and HB zeolite.[56] The Cu–Zn–Al oxide was a catalyst for methanol synthesis, while the HB zeolite was used for the further transformation of methanol intermediates. However, the composite catalyst turned out to inefficiently yield C_{2+} hydrocarbons. After the HB zeolite was modified with 1,4-bis(hydroxydimethylsilyl)benzene, the zeolite surface was turned hydrophobic to significantly improve the yield of C_{2+} hydrocarbons. The hydrophobic surface of the HB zeolite suppressed the deactivation of strong acidic sites, thereby enhancing the catalytic selectivity to C_{2+} hydrocarbons.

4. Regulating C–C coupling in CO_2 electroreduction

4.1 A brief overview of CO_2 electroreduction

Compared to syngas conversion and CO_2 hydrogenation, CO_2 electroreduction proceeds under milder reaction conditions, which does not require hydrogen feeding, high temperature and high pressure any more. Moreover, CO_2 electroreduction can be driven by the electricity generated by solar and wind energy, which contributes to the full utilization of geographical, seasonal and intermittent renewable energy sources.[1,9] For this reason, CO_2 electroreduction is a particularly appealing approach to CO_2 conversion which has been extensively explored in recent years.

Electrocatalytic CO_2 reduction is typically performed in a three-electrode H-cell consisting of a working electrode, a counter electrode and a reference electrode. In order to obtain

high currents, electrocatalysts can be dispersed onto a gas diffusion electrode and function in a flow cell.[57,58] Metal-based catalysts are commonly used for CO_2 electroreduction, whose products highly depend on catalyst compositions. Au, Ag, Zn and Pd mainly generate CO products, while Pb, In, Sn and Bi are typical catalysts for the production of formic acid or formate (in basic electrolytes).[1,9] Cu is the only known metal which can catalyze CO_2 electroreduction to C_{2+} products with reasonably high efficiencies.[59] Although some carbon materials can also generate C_{2+} products, the current density of C_{2+} products is relatively low compared to that of Cu.[60] Other Cu-based compounds and composites such as Cu_2S,[61] Cu_3N[62] and Cu–C_3N_4 (ref. 63) have also been explored for electrocatalytic CO_2 reduction. Moreover, the electrochemical conversion of CO, regarded as a key intermediate to form C_{2+} products in the CO_2 electroreduction process, can also be catalyzed by Cu.[64] In both cases, the electroreduction of CO_2/CO has to compete with the undesired side reaction – hydrogen evolution reaction (HER) – because most electrochemical reaction cells use inorganic salt (*e.g.*, $KHCO_3$, $NaHCO_3$, and Na_2SO_4) aqueous solutions as electrolytes.[9] Interestingly, C_{2+} products cannot be produced on Cu catalysts thermochemically while C–C coupling can be achieved electrochemically. In fact, Cu catalysts have been widely studied for the RWGS reaction,[51] but the Cu surface only provides active sites for nondissociative activation of the CO generated from CO_2. As a result, the CH_x species cannot be formed for a further C–C coupling process. In an electrochemical reaction, the CO intermediates generated from CO_2 also undergo nondissociative activation, but C–C coupling and the subsequent protonation can be driven by applying electrical energy on the Cu surface.

Specifically during CO_2 electroreduction, the $CO_2^{\bullet-}$ intermediate is firstly formed by transferring one electron to CO_2. As rearranging a linear CO_2 molecule to a bent radical anion needs to overcome a high energy barrier, and this step is regarded as the rate-determining step (RDS) for most transition metal-based catalysts. The highly reactive $*CO_2^{\bullet-}$ intermediate then undergoes proton-coupled electron–transfer reactions to form different products. Pb, In, Sn and Bi-based catalysts primarily generate $HCOO^-$ as their surfaces show weak binding to the $*CO_2^{\bullet-}$ intermediate. In comparison, Au, Ag, Zn and Pd-based catalysts bind to the *CO intermediate too weakly so CO is the major product. Among various catalysts, Cu is a unique one which has the moderate binding energy of the *CO intermediate, and as such, the following hydrogenation and C–C coupling processes can occur on its surface.

Until now, 18 products including C_1 and C_{2+} products have been detected for CO_2 electroreduction using Cu-based catalysts,[65–67] among which C_2H_4, C_2H_6, CH_3CH_2OH and *n*-$CH_3CH_2CH_2OH$ are four main C_{2+} products reported in the literature. The mechanisms for CO_2 electroreduction on the surface of Cu-based catalysts have been investigated by many theoretical and experimental studies.[68–72] However, the formation mechanism for deep reduction products (>2e$^-$ transfer, including CH_4, CH_3OH, HCHO and C_{2+} products) has not been fully understood. According to the mainstream view, *CO is regarded as a key intermediate for the formation of deep reduction products. During the CO_2 electroreduction process, CO_2 is first activated and reduced to adsorbed CO (*CO), which can then be converted to CH_4 and CH_3OH through *COH and *CHO intermediates, respectively. As for the formation of C_{2+} products, several reaction pathways have been proposed,[69,73,74] including (1) *CO + *CO → *COCO → C_{2+} products, (2) *CO → *CHO; *CHO + *CO → *COCHO → C_{2+} products, and (3) *CO → *COH → CH_x → C_{2+} products. The first pathway, named the *CO dimerization pathway, is widely accepted for the formation of main C_{2+} products. In this mechanism, the C–C coupling through *CO dimerization that forms a negatively charged CO–CO^- species is regarded as the rate-determining step.[75] To improve the formation of C_{2+} products, the surface coverage of *CO intermediates should be enhanced. The CO–CO^- intermediate is further protonated to generate the *CO–COH intermediate, which has been confirmed by Koper *et al.* through *in situ* Fourier transform infrared spectroscopy (FTIR).[76] Then *CO–COH intermediates undergo a series of protonation and electron transfer steps to yield different products. According to theoretical calculation, the C_2H_4 pathway and C_2H_5OH pathway share the same intermediate, $*CH_2CHO$.[71] Nevertheless, tuning the energetics of $*CH_2CHO$ intermediate binding can shift the C_2H_4 pathway to the C_2H_5OH pathway. As for improving the formation of *n*-$CH_3CH_2CH_2OH$, a high surface coverage of C_2 intermediates should be ensured to promote the coupling of C_1–C_2 intermediates. The possible mechanistic pathways of CO_2 electroreduction to C_1 and C_{2+} products are summarized in Fig. 9.

4.2 Controlling crystal facets

The facet effects of Cu crystals are quite evident for electrocatalytic CO_2 reduction. Cu(111) facets predominantly produce CH_4 while Cu(100) facets preferentially generate C_2H_4. After early recognized by Hori *et al.*, this conclusion has been confirmed by many experiments and theoretical calculations. The DFT calculations showed that the atoms on Cu(100) stabilized the dimer of CO due to their unique orientation, selectively promoting C_2H_4 formation.[77,78] In sharp contrast, Cu(111) facets favor the protonation of CO to COH,[74,79,80] mainly producing CH_4. Koper and coworkers used online electrochemical mass spectrometry (OLEMS) to detect gaseous products formed on Cu(100) and Cu(111) surfaces during the CO electroreduction.[81] They found that ethylene was formed at −0.3 V on Cu(100), while a potential of −0.6 V was required for Cu(111), confirming that Cu(100) facts prefer to produce ethylene (Fig. 10). Cu(110) facets were found to promote the formation of hydrocarbons in electrocatalytic CO_2 reduction. Yin and coworkers successfully synthesized Cu nanocrystals with a rhombic dodecahedral shape and enriched high-energy (110) facets by a chemical etching method.[67] As compared with the Cu nanocubes mainly enclosed by (100) facets, the obtained Cu rhombic dodecahedra exhibited higher faradaic efficiencies toward CH_4, C_2H_4, C_2H_6 and C_3H_8. This suggests that the high-energy (110) facets more favor the formation of hydrocarbons than (100) facets. In addition, some high-index planes such as (911) and (711) have been predicted to promote C_2H_4 formation and suppress CH_4 formation.[81,82]

4.3 Tuning catalyst sizes

The size effects of Cu spheroidal particles and Cu cubes have been studied in previous reports. Strasser and coworkers first explored the size effects of Cu nanoparticles in electrocatalytic CO_2 reduction.[83] They prepared a series of Cu spheroidal nanoparticles in the mean size range of 2–15 nm. While the obtained Cu spheroidal nanoparticles were tested in CO_2 electroreduction, a spherical particle model was built to gain deep insights into experimental trends in the activity and selectivity for CO_2 electroreduction as a function of particle size (Fig. 11a and b). When the size was below 2 nm, the number of under-coordinated atoms with a coordination number (CN) < 8 was drastically increased on the surface of Cu particles. This enabled the strong binding of intermediate reaction species such as CO and H to the catalyst surface. As a result, the faradaic

efficiencies for CO and H_2 production were substantially higher compared to that of Cu foil (Fig. 11c and d). When the Cu particle sizes were between 5 and 15 nm, the spherical particle model predicted that the populations of (100) (CN = 9) and (111) (CN = 8) facets were kept low and constant. This trend was consistent with the corresponding constant faradaic efficiencies for hydrocarbons. In the case of larger Cu spherical particles, the weaker binding of CO and H to their surface favored the formation of methane and ethylene.

In another example, Loiudice *et al.* prepared Cu cubes with edge lengths of 24 nm, 44 nm and 63 nm which exposed (100) facets predominantly.[84] During electrocatalytic CO_2 reduction, the cubes with the 44 nm edge length offered the best performance, with 80% selectivity toward CO_2 reduction and 41% faradaic efficiency for C_2H_4 production (Fig. 11f). Fig. 11e shows the analysis for a simple Cu nanocube model. As the size increases, the relative number of atoms on (100) planes is promoted at the expense of corner and edge atoms. Specifically, the ratio of edge sites over (100) plane sites can be optimized to achieve the highest selectivity for CO_2 reduction and C_2H_4 formation.

4.4 Forming bimetallic catalysts

Cu-based bimetallic catalysts have been widely explored for CO_2 electroreduction.[85] Typically, bimetallic catalysts offer two active sites on the surface – one for CO generation and the other for C–C coupling, which promote the production of C_{2+} products. For instance, Ren *et al.* reported that an oxide-derived Cu_4Zn catalyst could produce ethanol with a remarkably high faradaic efficiency (29.1%, among the highest reported values for ethanol production) at −1.05 V *vs.* RHE.[86] In that case, Zn acted as the site for CO production so the generated CO migrated to neighboring Cu active sites and underwent C–C coupling to produce ethanol.

Similarly to syngas conversion (Fig. 4), the surface atomic mixing pattern of two metals plays a crucial role in C–C coupling to generate C_{2+} products in CO_2 electroreduction. For instance, Ma *et al.* synthesized a series of Cu–Pd bimetallic catalysts with ordered, disordered and phase-separated atomic arrangements (Fig. 12a and b).[87] As shown in Fig. 12c and d, the phase-separated sample exhibited the highest faradaic efficiency (up to 63%) to C_2 products including ethylene and ethanol, while the ordered sample mainly generated C_1 products and showed the lowest faradaic efficiency (<5%) to ethylene and ethanol. This work proposed that neighboring Cu atoms on the surface of phase-separated Cu–Pd catalysts favored the formation of C_2 products while the alternating Cu–Pd sites on the surface of ordered and disordered samples promoted CH_4 production.

It is worth pointing out that the compressive strain induced by the formation of a surface alloy may have a great influence on C–C coupling, leading to a significant change in the distribution

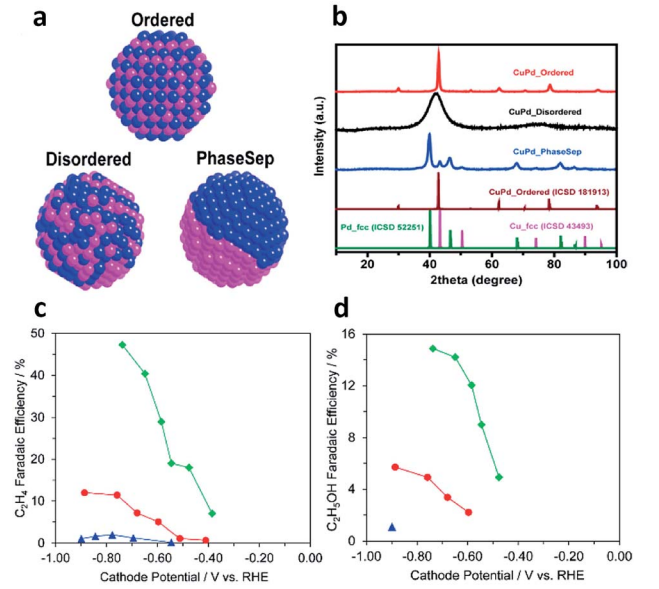

Fig. 12 (a) Schematic illustration of CuPd nanoalloys with ordered, disordered and phase-separated structures. (b) XRD patterns of the prepared CuPd nanoalloys. Faradaic efficiencies of (c) C_2H_4 and (d) C_2H_5OH for bimetallic Cu–Pd catalysts with different mixing patterns: ordered, blue; disordered, red; phase-separated, green. of products. According to the work by Bell and coworkers,[88] the formation of a Cu–Ag surface alloy induced compressive strain between surface Cu atoms. As a result, the compressive strain modified the electronic structure of the catalyst by shifting the valence band structure of Cu to deeper levels, reducing the binding energies of H and O relative to that of CO. Thus, the H_2 production was obviously suppressed (60–75% reduction) while the faradaic efficiency of C_{2+} products was increased by 10–15%. Moreover, the production of multi-carbon carbonyl-containing products was enhanced at the expense of ethylene, as the modification of the electronic structure reduced the coverage of adsorbed H atoms and the oxophilicity of compressively strained Cu sites.

4.5 Confining catalysis on the internal surface

Porous catalysts such as nanopores and nanocavities offer a confined environment. The diffusion, adsorption and desorption of reactants, intermediates and products are strongly affected due to the geometrical constraints, thereby tuning the selectivity and activity for some specific reactions. Owing to the confinement effects, the reactions occurring on the internal surface of nanopores and nanocavities show unique characteristics. As such, fabricating nanoporous electrocatalysts has the potential to improve the production of C_{2+} products.

For instance, Sargent and coworkers proposed that C_2 intermediate species could potentially be concentrated inside a nanocavity structure owing to steric confinement.[89] As such, the desorption of C_2 intermediates was limited by the internal surface of the nanocavity so further conversion into a C_3 product could be promoted. This argument was supported by simulations using the finite-element method. The simulations revealed that the suppression of C_2 intermediate desorption by the cavity increased the surface coverage and residence time of the intermediates, favoring C_3 formation. Guided by this simulation finding, they fabricated a series of nanocavity Cu catalysts with different hole sizes for CO electroreduction (Fig. 13a and b). Using the nanocavity copper catalyst with an appropriate hole size, the faradaic efficiency of propanol could reach 21 ± 1% at −0.56 V *versus* RHE, with a partial current density of 7.8 ± 0.5 mA cm^{-2}. In another case, Yang *et al.* fabricated three Cu mesopore electrodes with mesopores of 30 nm width and 40 nm depth (30 nm/40 nm), 30 nm width and 70 nm depth (30 nm/70 nm), and 300 nm width and 40 nm depth (300 nm/40 nm) for CO_2 electroreduction.[90] Compared to the 300 nm/40 nm electrode, the 30 nm/40 nm electrode exhibited enhanced ethylene formation with faradaic efficiency from 8% to 38%. As the pore depth was further increased to 70 nm (30 nm/70 nm electrode), the major C_2 product was converted to ethane, giving 46% faradaic efficiency. This change in product selectivity was ascribed to the alteration of local pH and retention time of key intermediates inside the pores caused by the confinement effect.

4.6 Engineering catalyst defects

Defects, which can be classified into point defects, line defects, plane defects and bulk defects, exist widely in materials. Creating defects on the surface of catalysts can alter the electronic and surface properties of the catalyst, thereby influencing the catalytic activity and selectivity.[91,92] In terms of CO_2 electroreduction, engineering catalyst defects, such as heteroatom dopants, vacancies and grain boundaries, is a promising approach to promote C–C coupling toward improved selectivity for C_{2+} products.[91]

As a powerful approach, doping heteroatoms can modify the surface electronic structure of Cu sites, enabling control over CO adsorption and dimerization. The Sargent research group demonstrated that doping boron on a Cu-based catalyst surface could induce and stabilize $Cu^{\delta+}$ sites,[93] regarded as the active sites responsible for C_2 product production (Fig. 14a).[94,95] The ratio of $Cu^{\delta+}$ to Cu^0 active sites could be tuned by varying the boron dopant content. As the average copper valence state was tuned to +0.35, a maximum faradaic efficiency (nearly 80%) for C_2 products was achieved on boron-doped Cu catalysts at −1.1 V *versus* RHE (Fig. 14b and c).

Vacancy defect engineering is another versatile strategy for tailoring the electronic structure of neighboring atoms, thereby altering the energy barriers of the rate-limiting reaction intermediates.[96] As such, creating vacancy defects on the catalyst surface has the potential to drive CO_2 reduction to specific C_{2+} products. Sargent and coworkers reported that a Cu_2S–Cu–V structure, with a Cu_2S core and a shell containing Cu vacancies (Fig. 15a–g), significantly shifted the product selectivity away from ethylene toward ethanol and propanol.[61] Previous mechanism studies indicated that the reaction intermediate $*C_2H_3O$ could follow two different pathways to form ethylene and ethanol, respectively.[71] Theoretical simulations revealed that the creation of vacancies on the Cu shell with a Cu_2S core increased the energy barrier in the ethylene pathway (1.148 eV),

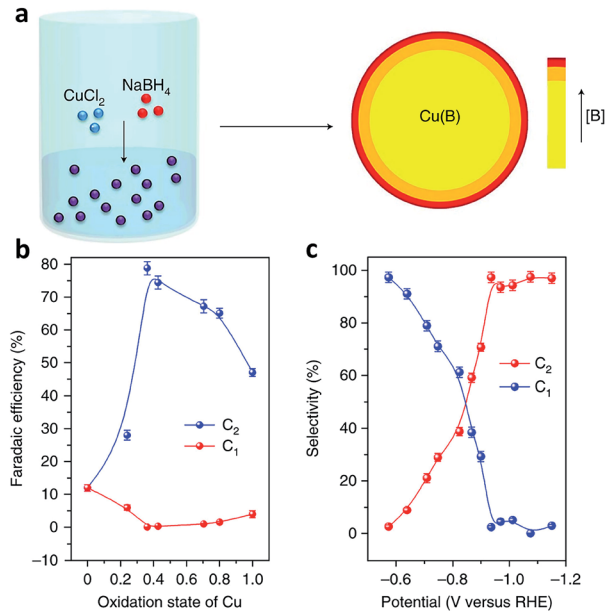

Fig. 14 (a) Schematic illustration of the synthesis of B-doped Cu by a wet-chemical process. (b) Faradaic efficiency of C_2 and C_1 products *versus* the oxidation state of Cu. while the ethanol formation pathway was mostly unaffected (0.427 eV). Such a design achieved a faradaic efficiency of 32% for C_{2+} alcohols (C_2H_5OH 25 ± 1% and C_3H_7OH 7 ± 0.5%) by steering post-C–C coupling selectivity through vacancy defect engineering.

Defect engineering has also been proven effective for tuning CO electroreduction. The Kanan research group demonstrated that up to 57% Faraday efficiency of C_{2+} oxygenates (ethanol, acetate and *n*-propanol) could be achieved for CO electroreduction on oxide-derived Cu catalysts at modest potentials.[64] The excellent selectivity to C_{2+} oxygenates was enabled by the participation of grain boundary surfaces in the CO electroreduction process. The same research group further proved that the activity for CO electroreduction was directly correlated with the density of grain boundaries in Cu nanoparticles. Increasing the grain boundary density would promote the selectivity to ethanol and acetate linearly.[97] Using isotope labelling, Ager and coworkers found that there may exist three different types of active sites on oxide-derived Cu catalysts, which accounted for the formation of C_{2+} products – ethylene, ethanol/acetate and 1-propanol, respectively.[65] As proposed in their work, three product-specific active sites may be formed by the three different types of grain boundary termination.

5. Conclusions and outlook

CO_x conversion is a highly important research theme for achieving the carbon cycle. As estimated in a most recently published perspective article,[98] an ideal catalytic process needs to be powered by electricity emitting less than 0.2 kg of CO_2 per kW h to achieve a net reduction in CO_2. To make electrocatalytic CO_2 reduction appealing for practical applications, the reaction rates for CO_2 conversion should be elevated by two orders of magnitude. While this estimation was mainly based on the product of methanol, it highlights the necessity of substantially improving the reaction activity. Nevertheless, very differently from many other catalytic reactions (*e.g.*, ammonia synthesis), the major challenges for CO_x conversion originate from both reaction activity and selectivity. Once activated, CO_2 and CO molecules may evolve into many different products. For this reason, fundamental research for CO_x conversion is often focused on the control over product selectivity, which relies on catalytically active sites from the perspective of surface science. The central theme for controlling product selectivity in such a reaction system is to precisely achieve C–C coupling.

In this sense, rational design of catalysts based on surface science is a key strategy for precisely achieving C–C coupling in both thermocatalytic and electrocatalytic CO_x conversion. In this article, we have reviewed typical catalyst design strategies based on surface science for tuning C–C coupling in syngas conversion, CO_2 hydrogenation and CO_2 electroreduction, aiming to obtain the targeted C_{2+} products such as olefins, long-chain hydrocarbons and higher alcohols with high selectivity. Such surface science-based design strategies include the means of controlling crystal facets, tuning catalyst sizes, forming bimetallic catalysts and others, which can significantly alter the

structural and electronic properties of thermocatalysts and electrocatalysts.

As a matter of fact, it still remains the biggest challenge to precisely regulating C–C coupling toward the targeted C_{2+} products in thermocatalytic and electrocatalytic CO_x conversion. This challenge has been especially emphasized for the approach of CO_2 electroreduction. The selectivity for hydrocarbons or higher alcohols produced from CO_2 electroreduction is too low and far from meeting the requirements of industrialization. Syngas conversion has witnessed a long research history and been put into practice in large-scale industrialization. Until now, the research on syngas conversion has continued its success, and many breakthroughs have been made by optimizing catalyst design based on surface science, especially using bifunctional catalysts. As such, many studies on CO_2 hydrogenation have drawn lessons or been enlightened from the experience of syngas conversion, greatly promoting the development of CO_2 hydrogenation. We think that the significant research progress of syngas conversion and CO_2 hydrogenation will provide very instructive information for the development of CO_2 electroreduction particularly from the viewpoint of C–C coupling. The design of bifunctional catalysts based on surface science has the potential to make another breakthrough in CO_2 electroreduction, just like the case of Jaramillo and coworkers where a tandem gold-on-copper electrocatalyst offers gold for CO generation and copper for further CO reduction to alcohols.[99]

Although the three reaction systems share many similar working mechanisms, catalysts should be specifically designed for a final application as the material requirements differ from case to case owing to reaction phases and energy input. As a result, the specific working mechanisms should be fully examined for each case, which can be facilitated through collaborative research at the intersection of controlled synthesis, advanced characterization and theoretical simulation. This multidisciplinary research mode has demonstrated its success in CO_x conversion in the past few years. In many cases, the bottleneck for mechanistic studies comes from the limitation of operando spectroscopic techniques. The advanced spectroscopic techniques help *in situ* characterization of the dynamic evolution of active sites and reaction intermediates on the catalyst surface at atomic/molecular levels. Future development of characterization techniques would be more focused on spatial and temporal resolution. Certainly these challenges will be accomplished, and plentiful opportunities exist in these fields. The importance of CO_x conversion to society and industry will continue motivating the research toward controllable and scalable production.
